By reason of the arrangements above described and the ionizing of the gas in the evacuated vessel or bulb U due to the presence within said vessel of the hot or glower electrode F, and by impressing an electromotive force within the space between the cold plate or wing electrodes W and the hot electrode from the current source B, the device U, with its electrodes and their associated circuits and circuit connections as described becomes a generator of oscillating, alternating or pulsating electric currents which are impressed upon the circuit which connects the grid and plate electrodes, the frequency of which depends upon the condition of the gas within the vessel U, the spatial relation of the electrode member contained therein, the value of the electromotive force impressed across the electrodes, and the amount of inductance and capacity in or associated with the circuit connection between the cold electrodes. This frequency may be varied by adjusting the capacity or inductance in said circuit connection.

By reason of the association of the oscillating circuit connecting the cold electrodes with the antenna earth system N E the oscillating, alternating or pulsating currents in said circuit connection are impressed upon said antenna earth system and with a natural period of oscillation in said circuit, the same as that in said oscillating circuit. The emission of wave trains from the antenna earth system may be controlled in accordance with the telegraphic code through the telegraph key K, which acts to short circuit a portion of the inductance S. Or, if desired, the amplitude of the oscillations induced in the antenna earth system may be varied by and in accordance with sound waves falling upon the microphone transmitter M in the usual manner. It is obvious that the wave length of the emitted wave trains may be altered in a manner well understood in the art.

I am unable at the present time to give a wholly satisfactory explanation of the theory of the generator action of the apparatus. I have discovered, however, as hereinbefore stated that a system constructed as shown and described and energized from a suitable current source becomes the seat of continuous oscillations and it is my opinion that the phenomenon depends upon the inductive effect of successively applied charges or surges of potential upon the grid and plate electrodes which charges or surges have the power to affect momentarily the conductivity of the surrounding or inter-connecting gas medium within the vessel in such manner that the action, when set up, is self perpetuating.

From the foregoing description it will be observed that in its broad scope my invention lies in the discovery that when suitably connected and associated an audion becomes a generator of oscillating, alternating, or pulsating electric currents which may be utilized for any purpose for which such currents are desired, and I have succeeded in securing remarkable results in the practical use and operation of an oscillation generator of this character particularly when applied to the generator of high frequency oscillations.

It is obvious that the principles of my invention may be embodied in various arrangements and circuit connections without departure from the spirit and scope of my invention as defined in the claims, but

Having now set forth the objects and nature of my invention and circuit arrangements embodying the principles thereof, what I claim as new and useful and of my own invention, and desire to secure by Letters Patent, is—

1. The combination with an evacuated vessel, of a plurality of wing elements; a

plurality of grid elements, and a hot electrode arranged therein, a grid element being arranged between each wing element and the hot electrode.

2. An audion having a plurality of grid electrodes, a plurality of wing electrodes, and a hot electrode.

3. An audion having a plurality of grid electrodes, a plurality of wing electrodes, and a hot electrode, a grid electrode being interposed between each wing electrode and the hot electrode.

In testimony whereof I have hereunto set my hand in the presence of the subscribing witnesses, on this 21st day of December, A. D., 1915.

welded or hard soldered to platinum wires sealed into the glass bulb D. A lies on the axis of a cylindrical electrode E of metal foil, or, preferably, gauze supported by the sealed-in lead F. The tube H enables the bulb to be exhausted and sealed off or connected to the apparatus for supplying various gases, measuring the pressure, etc. The precise construction of such a bulb depends on the nature of the substance A experimented with. If A is a platinum wire then all the metal parts inside the bulb are best made entirely of platinum. The whole apparatus can then be thoroughly cleaned with boiling nitric acid and distilled water. Tungsten filaments require to be electrically welded, in an atmosphere of hydrogen, to the stout leads which may be of iron or copper. Carbon filaments have to be joined with paste as in constructing incandescent lamps. Most other materials are to be welded to the supports if possible, otherwise hard soldering may be employed. In experiments of this character it is often of the utmost importance not merely to secure the chemical purity of the materials used, but to make sure that not even the smallest traces of gases are liberated in the bulb during the course of the experiments. The best way of accomplishing this is to heat the tube D to a high temperature whilst it is exhausted by a Gaede pump, assisted by a liquid air and charcoal condenser. Meanwhile the wire A is glowed out electrically, and, in order to drive every trace of gas out of the cylindrical electrode E, it is desirable that this should be heavily bombarded by cathode rays, obtained by applying a high negative potential to A. To maintain the tube D at a high temperature without its collapsing under the external pressure during the exhaustion, it should be heated in a vacuum furnace. A suitable form of furnace may be constructed with a heavy water jacketed brass base provided with holes for the tube H and the leads B, C, and F. The holes can be made airtight with glass and seal-

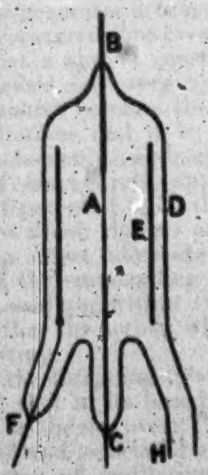

Fig. 1.

ing-wax, and an additional hole for the insertion of a platinum thermometer or thermocouple is desirable. On the base rests a large cylindrical brass bell jar, the line of contact being made airtight with a rubber gasket. The brass cylinder is balanced by weights attached to ropes passing over pulleys so that it can easily be moved up and down. The furnace itself is inside the brass cylinder, and rigidly attached to it. It consists, starting from the inside, of a vertical cylinder of some non-oxidizable metal such as monel metal or nickel; this is insulated by a layer of mica, over which is a winding of nichrome strip having a suitable resistance and current-carrying capacity. Between the nichrome winding and the outer brass cylinder is a thick packing of fireclay and asbestos. The leads to the nichrome strip and the exhaust can be let in through the cover of the brass cylinder. This, as well as the brass base, should be water cooled. With such an arrangement, with the furnace exhausted to a pressure of about 1 cm., the experimental bulbs can be exhausted for several days at a temperature of about 570° C. without collapsing. A vacuum furnace of this type in actual operation is shown in Fig. 2.

Many experiments can be made without taking these elaborate precautions, but we shall see later[1] that if we wish to be sure of obtaining the effects which are characteristic of the pure metals in the absence of a gaseous atmosphere we cannot afford to dispense with the manipulation just described.

Almost all the phenomena under consideration are very sensitive to small changes in temperature; so that even when it is not necessary to know the actual temperature of the filament A it is essential that it should not vary. A very sensitive temperature control is provided by a method which involves the measurement of the resistance of the filament. For this purpose, in carrying out the experiments, the filament is made to form one arm of a Wheatstone's bridge which is actuated by the battery supplying the heating current. The arrangement of apparatus for measuring the thermionic current which flows from the filament A to the cylinder E is shown diagrammatically in Fig. 3. K, L, and M are the three other resistances which form the arms of the Wheatstone's bridge,

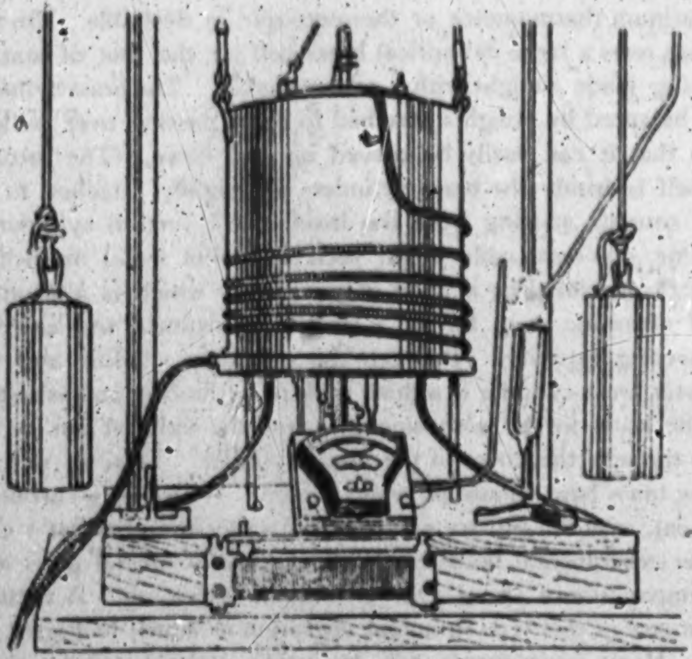

FIG. 2.

the bridge galvanometer G being provided with the key N.

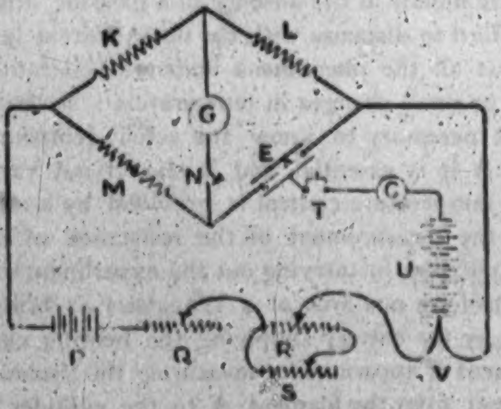

FIG. 3.

The main heating current is supplied by the battery P and to eliminate traces of gas from apparatus containing ground glass joints; so that this type of apparatus is useful only when the effects of such traces of gas are relatively unimportant.

A convenient arrangement for making rapid qualitative tests of the sign of the ions emitted by hot wires has recently been described by Hopwood.[1] This consists in bringing an electrically-charged rod near a long loop of the electrically-heated wire which is connected to earth. The loop will only be deflected provided it does not emit ions of the sign opposite to the charge on the rod.

RELATION BETWEEN THE CURRENTS AND ELECTRO-MOTIVE FORCE AND GAS PRESSURE.

The first experimental investigation of this question was made by McClelland[2] with an arrangement similar to Fig. 1 in its main features. In all these experiments the temperature of the filament is kept constant and the general character of the results to be described is independent of the nature of the material used, provided that the filaments have been heated for a considerable length of time (see pp. 60 and 182). At pressures comparable with atmospheric the relation between the current and the difference of potential maintained between the filament and the cylinder is similar to the left-hand half of the curve shown in Fig. 4, although this figure actually refers to another case. With low voltages the current is proportional to the applied potential difference, but as the potential difference increases, the rate of increase of the current gradually falls off until finally saturation is attained. There is thus a definite limit to the number of ions liberated by the glowing filament in unit time. In air at low temperatures this description applies only when the filament is positively charged; there is no appreciable current when the wire is charged negatively. At higher temperatures similar results are obtained whether the filament is charged positively or negatively, the ratio between the saturation current with the wire negative and that with the wire positive increasing continuously with rising temperature. In these respects the observations agree with the earlier experiments described on page 3.

---

[1] "Phil. Mag.," Vol. XXIX, p. 362 (1915).

[2] "Camb. Phil. Proc.," Vol. XVI, p. 296 (1901).

With pressures of the order of 1 millimetre of mercury the current-E.M.F. curves were found to be entirely different. With the filament negatively charged there was no indication of saturation. The current in general increased more rapidly than the first power of the potential difference. The effects observed with a *positively* charged wire at these pressures are exhibited in Fig. 4. which actually refers to this case. At intermediate voltages there is evidence of saturation, but this stage is succeeded by a stage in which the current again increases with rising potential difference.

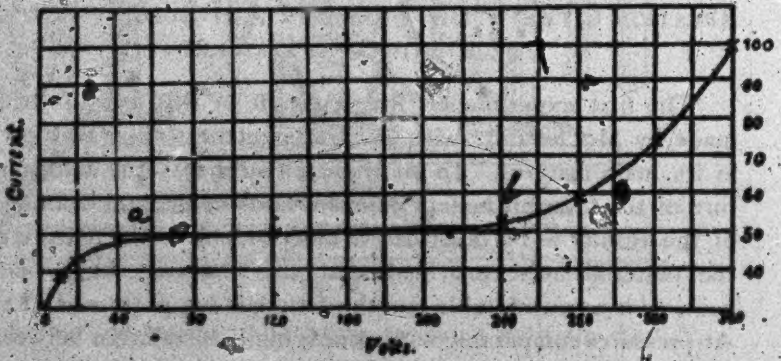

Fig. 4.

McClelland showed that these phenomena could be explained in a general way on the hypothesis that the ions liberated at or near the surface of the filament were able, under the accelerating influence of the electric field, to produce new ions by impact with the neutral molecules with which they collided. In the case of the positive ions this increase in the current due to ionization by impact did not begin to make itself felt, in the example shown in Fig. 4, until there was a difference of potential of over 200 volts between the electrodes. The existence of saturation with lower potentials showed that all the ions initially liberated were being collected by the cylinder, and, as the current was independent of the electromotive force in this region, there was no additional current depending on the energy of the impacts. The absence of saturation with the currents from the negatively charged wire makes it necessary to suppose that ionization by collision sets in before the stage at which saturation is reached. Thus the part *a*, *b* of the curve in Fig. 4 is missing when the wires are charged negatively. Another consequence of this interpretation is that ionization by impact is effective with a smaller fall of potential for negative than for positive ions. The hypothesis of ionization by impact had previously been put forward by Townsend and J. J. Thomson to account for somewhat similar phenomena exhibited by other sources of ionization. McClelland's experiments seem, however, to have first indicated definitely that positive ions could give rise to new ions by collision.

A more detailed examination of the relation between current, pressure, and electromotive force with negatively charged wires has been made by H. A. Wilson.[1] Some of the results obtained by Wilson at pressures ranging from 0·0036 mm. to 760 mm. are shown in Figs. 5 and 6. If the increase of current beyond the horizontal line corresponding to the lowest pressure (0·0036 mm.) is due to ionization by collision, Wilson showed that, according to Townsend's theory,

$$\log n_b/n_a = \frac{V}{E \log b/a}\left\{e^{-(NEpa/V)\log b/a} - e^{-(NEpb/V)\log b/a}\right\} \qquad (7)$$

provided $V/pa \log b/a$ is greater than 200. In this equation n_b is the number of negative ions which reach the cylinder in unit time, n_a is the number emitted by the hot wire (of circular section) in the same time, V is the applied potential difference, p the gas pressure, b the radius of the cylinder, a that of the wire, N the number of ionizing impacts per moving ion per cm., and E the potential fall necessary to acquire the ionizing energy (ionizing potential). This formula was found to represent the experimental results satisfactorily, with N = 3·04 and E = 17·7 (volts). The values of the constants are in satisfactory agreement with those deduced by Townsend from experiments with ionized air at ordinary temperatures, when allowance is made for the difference in the number of molecules in unit volume of a gas at a definite pressure due to change in temperature. The results point to the rather important conclusion that ionization by impact depends solely on the nature of the molecules, and their distance apart, and has nothing directly to do with the temperature of the gas.

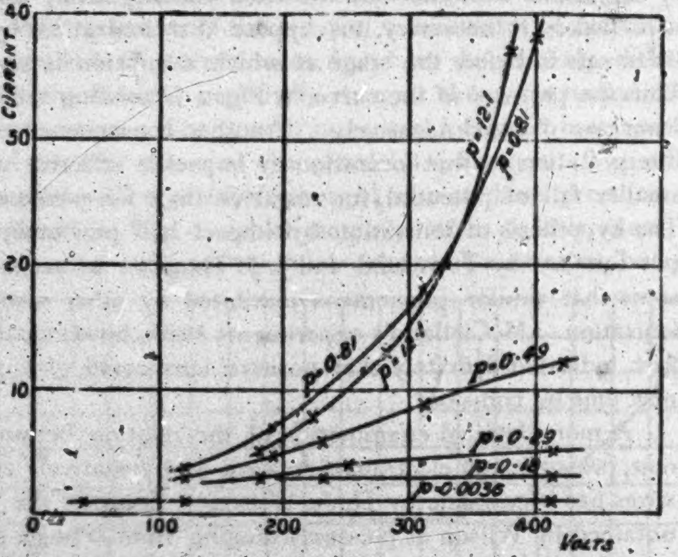

FIG. 5.

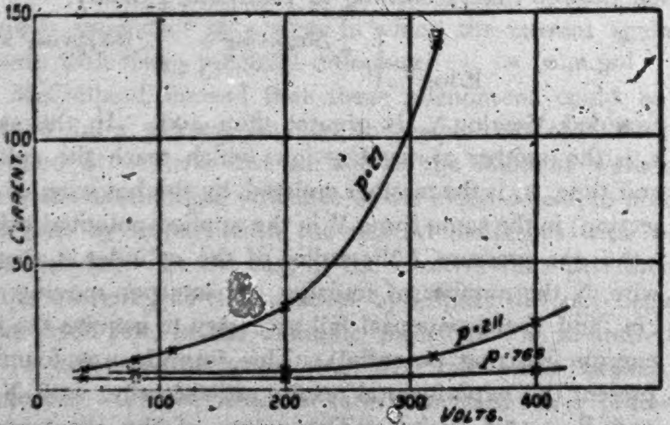

FIG. 6.

In this experiment the temperature must have been about the same as in the case to which Fig. 10 refers. The pressure is given as less than 0·001 mm. It will be seen that there is here no perceptible increase in the current between 25 and 180 volts.

It is only when the thermionic current densities are comparatively small that saturation is attainable with potential differences of 20 volts or under. With the large emissions which occur at very high temperatures the potential difference required for saturation may be very much higher owing to the mutual repulsion of the emitted electrons. This leads to an interesting effect which was discovered and explained by Langmuir.[1] In examining the thermionic current between two hairpin-shaped tungsten filaments, under fixed differences of potential, at various temperatures, the results exhibited in Fig. 11 were obtained. The experimental values lie along the broken curves, the continuous curve representing the saturation current at different temperatures. It will be noticed that the broken curves coincide with the continuous curve up to a certain temperature which is lower the smaller the applied potential difference. Beyond this point the currents are below the saturation value, but they still increase with increasing temperatures of the filament. At still higher temperatures the broken curves bend round, and the current under a given potential difference becomes entirely independent of the temperature of the hot filament. Owing to the mutual repulsion of the electrons a given difference of potential applied over given boundaries is only capable of forcing a definite number of electrons across the intervening space in unit time, no matter how many may be available.

In order more clearly to see how this comes about let us consider the simplest possible case, that of an emitting plane opposite a parallel conducting plane which represents the receiving electrode. Take the axis of x perpendicular to the planes and let V be the electrostatic potential at any point. Then the value of V is governed by Poisson's equation which reduces to

$$\frac{d^2V}{dx^2} = -4\pi\rho \qquad (7)$$

---

[1] "Phys. Rev.," Vol. II, p. 453 (1913).

ρ being the volume density of electricity at any point:

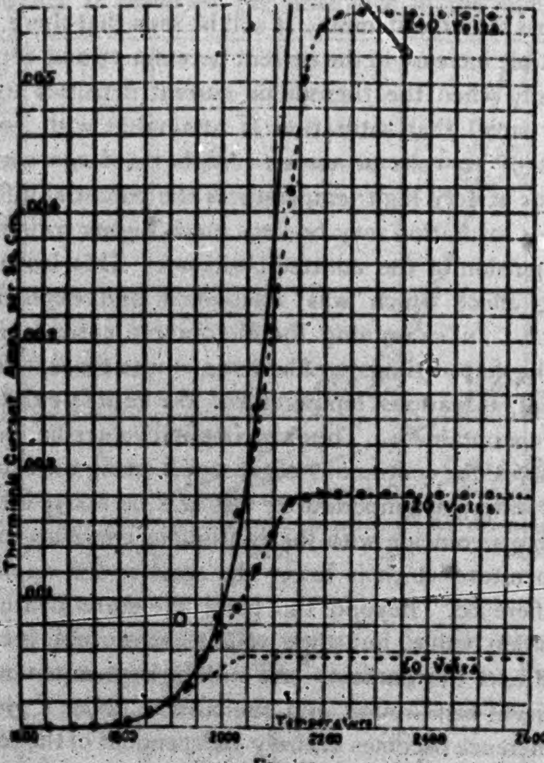

Fig. 11.

When there are no electrons emitted ρ is zero at every point;

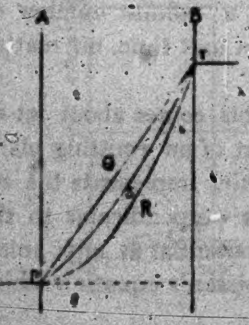

Fig. 12.

so that $\frac{dV}{dx}$ is constant and may be represented by the straight line PQT in Fig. 12. When the plate is emitting electrons these will give rise to a negative value of ρ in the space as they cross it, and if the number is small, the value of ρ thus arising will be approximately independent of x; so that the right-hand side of (7) will be a positive constant and the graph of V will be approximately parabolic and similar to PST. As he current and $-\rho$ increase this curve will sink below PQT until the stage PRT is reached, where the tangent at P is horizontal. Any further increase in the supply of electrons will now have no effect on the distribution of potential between the plates because there is nothing to drag them away from AP. We here assume that the emission velocities of the electrons are small compared with those which they acquire under the influence of the field; so that the results will only be true for fairly large potential differences (see Chapter V).

Now let us see how the current will depend on the applied potential when the condition that $\frac{dV}{dx}$ vanishes at the hot plate is satisfied. Let $+ e_1$ denote the numerical value of the negative charge of an electron and $+ \rho_1$ the numerical value of the negative density of charge at any point. An electron at a point when the potential is V (if $V = 0$ at the hot plate) will have acquired an amount of kinetic energy given by the equation

$$\tfrac{1}{2} mv^2 = Ve_1 \quad . \quad . \quad . \quad . \quad (8)$$

The current per unit area carried by the electrons at that point will be

$$i = v\rho_1 \quad . \quad . \quad . \quad . \quad . \quad (9)$$

and equation (7) may be written

$$\frac{d^2V}{dx^2} = 4\pi\rho_1 \quad . \quad . \quad . \quad . \quad . \quad (10)$$

By elimination of ρ and v from (8), (9), and (10)

$$\frac{d^2V}{dx^2} = 2\pi i\sqrt{\frac{2m}{e_1 V}}$$

and integrating, subject to $\frac{dV}{dx} = 0$ when $V = 0$,

$$\left(\frac{dV}{dx}\right)^2 = 8\pi i\sqrt{\frac{2mV}{e_1}} \quad . \quad . \quad . \quad . \quad (11)$$

By integrating again, subject to $V = 0$ when $x = 0$, and solving for i we find

$$i = \frac{\sqrt{2}}{9\pi}\sqrt{\frac{e_1}{m}}\,\frac{V^{3/2}}{x^2} \quad . \quad . \quad . \quad (12)$$

The same general method of treatment with the appropriate modification of Poisson's equation can be applied to the case of a circular wire surrounded by a coaxial cylinder, giving

$$i = \frac{2\sqrt{2}}{9}\sqrt{\frac{e_1}{m}}\frac{V^{3/2}}{r\beta^2} \quad . \quad . \quad (13)$$

when r is the radius of the cylinder, and

$$\beta = \log\frac{r}{a} - \frac{2}{3}\left(\log\frac{r}{a}\right)^2 + \frac{11}{120}\left(\log\frac{r}{a}\right)^3$$

$$- \frac{47}{3300}\left(\log\frac{r}{a}\right)^4 + \ldots,$$

a being the radius of the wire. In fact Langmuir[1] has shown from a consideration of the dimensions of the equations that, whatever may be the geometrical relation between the emitting and receiving electrode, the current under these circumstances will be equal to $V^{3/2}$ multiplied by a factor depending on e_1/m and the geometry of the system.

It appears then that over the flat part of the broken curves in Fig. 11 the current should be proportional to $V^{3/2}$. This requirement is found to be borne out by the experimental results; so that there can be no doubt of the adequacy of the foregoing explanation. Langmuir has suggested that experiments with concentric cylinders using equation (13) could be made so as to determine the value of e_1/m with great precision.

The effect of the mutual repulsion of the electrons in preventing the attainment of saturation will be important only when the saturation currents are of considerable magnitude; with sufficiently small currents this effect will vanish. We shall see in Chapter V that the electrons are emitted, not with zero velocity, but with a distribution of velocities whose mean square is proportional to the absolute temperature of the hot body. At 2000° K. this mean velocity is comparable with that which an electron would acquire by falling through a potential difference of about 0·25 volt. At relatively low temperatures when the emission is comparatively small, if the hot body is surrounded by the receiving electrode, we should expect saturation to be attained without the application of any potential difference; since all the electrons are emitted with some velocity, and any velocity, however small, will be sufficient to carry them across to the electrode ultimately. This supposition does not accord with the facts as observed in experiments with electrically heated wires surrounded by coaxial cylindrical electrodes. Under these conditions it is the writer's experience that potential differences comparable with two or three volts are required to cause saturation even when dealing with the smallest currents which are convenient to measure. There can be very little doubt that in these cases one cause operating against the attainment of saturation is the effect of the magnetic field, due to the heating current, on the motion of the electrons.

---

[1] Loc. cit.

To see how this comes about consider the case of a hot wire, of circular section and radius *a*, surrounded by a coaxial cylindrical electrode of radius *b*. Let V_1 be the potential difference in volts between the wire and the cylinder. The electric intensity R is everywhere radial and at distance *r* from the axis is given in electro-magnetic units by

$$R = V_1 \times 10^8/r \log b/a = A/r \quad . \quad . \quad (14)$$

The magnetic intensity H lies in circles about the axis of the wire, and, if *j* is the current in amperes, its value at distance *r* is

$$H = 2j/10r = B/r \quad . \quad . \quad . \quad . \quad (15)$$

On account of its direction the magnetic field will not affect the angular velocity of the electrons about the axis. Disregarding this rotation, the paths of the electrons are periodic curves, in the plane containing the axis, which keep intersecting the surface of the emitting cylinder. The effect of the neglected rotation is simply to convert these plane curves into spirals about the axis. There is a certain maximum distance, under given conditions, which an electron is able to travel from the axis, and unless this is equal to or greater than the radius of the outer cylinder the electrons will return to the surface of emission and will contribute nothing to the thermionic current.

If r is the perpendicular distance of an electron from the axis, z its distance from a fixed plane perpendicular to the axis, and θ the angle the plane containing the axis and the electron makes with a fixed plane through the axis, the equations of motion of the electron are:—

$$m\frac{\partial^2 r}{\partial t^2} - mr\left(\frac{\partial \theta}{\partial t}\right)^2 = \mathrm{R}e - \mathrm{H}e\frac{\partial z}{\partial t} = \frac{\mathrm{A}e}{r} - \frac{\mathrm{B}e}{r}\frac{\partial z}{\partial t} \quad . \quad (16)$$

$$m\frac{\partial^2 z}{\partial t^2} = \mathrm{H}e\frac{\partial r}{\partial t} = \frac{\mathrm{B}e}{r}\frac{\partial r}{\partial t} \quad . \quad (17)$$

$$\frac{\partial}{\partial t}\left(r^2\frac{\partial \theta}{\partial t}\right) = 0 \quad . \quad . \quad . \quad . \quad . \quad (18)$$

From (18)

$$\frac{\partial \theta}{\partial t} = \frac{a^2}{r^2}\dot{\theta}_0, \quad . \quad . \quad . \quad (19)$$

if $\frac{\partial \theta}{\partial t} = \dot{\theta}_0$ when $r = a$.

From (17)

$$\frac{\partial z}{\partial t} = \dot{z}_0 + \frac{\mathrm{B}e}{m}\log\frac{r}{a} \quad . \quad . \quad . \quad (20)$$

if $\frac{\partial z}{\partial t} = \dot{z}_0$ when $r = a$.

Substituting these values of $\frac{\partial \theta}{\partial t}$ and $\frac{\partial z}{\partial t}$ in (16) and integrating subject to

$$\frac{\partial r}{\partial t} = \dot{r}_0 \text{ when } r = a,$$

$$\frac{\partial r}{\partial t} = \left[\dot{r}_0^2 + a^2\dot{\theta}_0^2\left(1 - \frac{a^2}{r^2}\right) - \frac{\mathrm{B}^2e^2}{m^2}\left(\log\frac{r}{a}\right)^2 + \frac{2(\mathrm{A}e - \mathrm{B}e\dot{z}_0)}{m}\log\frac{r}{a}\right]^{1/2} \quad . \quad . \quad (21)$$

The maximum value r_m of r is given by $\frac{\partial r}{\partial t} = 0$ or from (21), after substituting the values of A and B in terms of V_1 and i, by

$$V_1 = 10^{-8} \log \frac{b}{a}\left[\frac{j^2e}{50m} \log \frac{r_m}{a} + \frac{j}{5}\dot{z}_0 - \frac{m\dot{r}_0^2 + ma^2\dot{\theta}_0^2\left(1 - \frac{a^2}{r_m^2}\right)}{2e \log {}^{r_m}\!/_a}\right] \quad . \quad . \quad (22)$$

Thus if r_m is to be just equal to the radius b of the outer cylinder,

$$V_1 = 10^{-8} \log \frac{b}{a}\left\{\frac{j^2e}{50m} \log \frac{b}{a} + \frac{j}{5}\dot{z}_0 - \frac{m\dot{r}_0^2 + ma\dot{\theta}^2{}_0{}^2\left(1 - \frac{a^2}{b^2}\right)}{2e \log b/a}\right\} \quad . \quad . \quad (23)$$

If V_1 has a value equal to or greater than this the electrons will reach the electrode and form part of the current, otherwise they will not do so. If j is very small the right-hand side of (23) is negative, indicating that the current will be able to flow against an opposing potential owing to the initial emission velocities. The point of immediate interest, however, is the first term, on the right-hand side of (23), which is always positive and is independent of the emission velocities. This shows that owing to the action of the magnetic field due to the heating current, a definite potential is necessary in order to drag the electrons across to the electrode. With thin wires, which require only a small current to heat them, this potential difference is unimportant. Thus if $b/a = 200$ and $j = 1$ ampere, V_1 is only about 0·2 volt. On the other hand, with thick wires, which require large heating currents, the necessary values of V_1 may be quite large.

Another important factor which has to be taken into account, especially with thin wires, is the drop of potential along the wire due to the flow of the heating current. This is usually comparable with 1 volt per cm. In order to ensure that no part of the wire is at a positive potential compared with the cylinder, it is necessary that the *positive* end of the wire should be at a potential at least as low as that of the cylinder. If the potentials are applied at the negative end of the wire, it will appear from this cause alone that an additional negative potential equal to the fall along the hot wire has to be applied in order to ensure complete saturation.

That the mutual repulsion of the electrons, the magnetic field due to the heating current, and the drop of potential along the wire, also due to the last-named cause, are the chief general factors which prevent the attainment of saturation is strikingly shown by some recent experiments by Schottky.[1] Using concentric cylinders the thermionic currents with small differences of potential, both accelerating and retarding, were measured under conditions such that the heating current was cut out at the instant of measurement. By means of a suitable in-and-out switch, operating continuously, matters were arranged so that no appreciable variation in the temperature of the wire ensued thereby. Under these conditions the drop of potential along the filament and the magnetic field due to the heating current are eliminated, and it was found that the current saturated at zero potential difference; except for an effect, which was smaller the lower the temperature and smaller the current, arising from the mutual repulsion of the emitted electrons. In determining the actual difference of potential between the wire and the electrode, it was found necessary to add to the apparent applied potential difference registered by the voltmeter, a difference of potential equal to the contact potential between the two metals used. Thus experiments of this kind can be used to measure contact differences of potential under good vacuum conditions without displacing the surfaces subject to test.

Schlichter,[2] by using methods of heating the electrode which do not involve the passage of an electric current through it, has been able to show that the electron current with 220 volts driving potential is only about 10-20 per cent greater than that under zero potential difference, when the hot metal has been thoroughly glowed out. The special conditions which affect the attainment of saturation in the case of freshly heated metals will be referred to again on page 182, Chap. VI.

---

[1] "Ann. der Phys.," Vol. XLIV, p. 1011 (1914).

[2] *Ibid.*, Vol. XLVII, p. 573 (1915).

causes which might give rise to the observed effects. No doubt these are partly caused by electrons and ions emitted by the hot surfaces on account of the high temperature, but they may also be due partly to ions emitted by chemical action. The actions are also greatly complicated by the presence of the hot vapours which must have properties similar to those of flames.

THE RELATIVE IMPORTANCE OF VARIOUS FACTORS IN CAUSING THE EMISSION OF ELECTRONS FROM HOT BODIES.

We have already considered three possible causes of electronic emission, namely: the escape of the electrons owing to the purely thermal increase of their kinetic energy (p. 27), the liberation of electrons as one of the products of chemical action (p. 49), and the complete photoelectric emission (p. 95). We have seen (p. 100) that the available photoelectric data indicate that the last of these is too small to account for the emissions which have been observed from hot bodies; so that unless and until fresh observations are made which tend to conflict with this conclusion, it does not appear necessary to consider this particular question further.

It remains to deal with the relative claims of the purely thermal effect and of chemical action. In the last few years a number of writers have advocated the view that all the observed effects are attributable to chemical action. The case for this position is, briefly, as follows:—

We have seen in Chapter II that any electronic emission arising from chemical action would be likely to follow a law of temperature variation practically identical with that required by the purely thermal effect; so that the fact that the theoretical law is satisfied by the experimental results offers no criterion for distinguishing between the two views. In certain cases there is some evidence that electrons are liberated as a direct result of chemical action between solids and gases. The experiments of Haber and Just[1] have shown that when the alkali metals, their alloys, or amalgams, are attacked by oxygen, hydrochloric acid gas, phosgene gas, water vapour, and certain other chemically active gases or vapours, electrons are liberated in considerable quantity. It may be urged (cf. Chapter IX, p. 290) that in reality this also is a thermal emission, caused by a local increase of temperature in the surface layer arising from the heating caused by the chemical action. Most of Haber and Just's experiments were made with drops of various amalgams and with the liquid alloy of sodium and potassium. From a determination of the amount of chemical action occurring they calculate that in a particular experiment the heat generated by the chemical action was not sufficient to raise the temperature of the whole of a drop more than 2° C. But it is clear that the temperature of the surface layers must have been raised to a very much greater extent, and as it is only the temperature of the surface layer which is of any account if the effect is a purely thermal one, it cannot be said that the experiments so far made by these authors prove that the emission is a direct consequence of chemical action. Similar conclusions to those of Haber and Just have been reached by Fredenhagen,[1] who has shown that the emission ordinarily observed when the alkali metals are heated can be reduced to very much smaller values by the careful elimination of gases. The smallest currents recorded by Fredenhagen are, however, not smaller than those calculated [2] by an application of the considerations on p. 40 to the known emission from platinum or tungsten, in spite of the strong electropositive character of the alkali metals. The large values are restored, at least partially, when small quantities of gases, and especially of oxygen, are allowed to come in contact with the metal. But when one remembers the extraordinary sensitiveness of the emission to changes of temperature and that, in any event, the effect is a purely superficial one, it is questionable whether the observed enhancement of the emission may not be due to the local increase of temperature caused indirectly by the chemical action. It is, of course, abundantly proved that an emission is caused by chemical action in these cases, but it is extremely difficult to be sure that the effect is the direct result of the chemical action and is not caused indirectly by the heat generated at the surface. (See, however, p. 296.)

The remaining cases which have been cited as examples of the emission of electrons by chemical action are the oxidation of calcium and the emission from incandescent carbon. Fredenhagen[1] has put forward the view that the activity of the lime-covered cathode is caused by the recombination of the calcium and oxygen which are separated by electrolysis during the passage of the current. The arguments in favour of this view have already been dealt with on p. 85 where they were not found to resist a critical examination successfully. We have already seen (p. 86) that Horton, who made a direct test of the question, was unable to detect any emission from calcium arising directly from oxidation. Wehnelt,[2] who has devoted much attention to the lime-covered cathode, has recently expressed the opinion that in the case of this material there is no evidence which would favour a chemical rather than a purely thermal cause for the origin of the emission. Finally, Germershausen[3] has shown that the emission from lime is increased by the removal of every trace of gas from its surroundings. Under these conditions the discharge becomes very similar to that from tungsten as observed by the writer and by Langmuir.

The emission from carbon has been attributed to chemical action between the carbon and traces of gaseous contamination by Pring and Parker,[4] and by Pring.[5] Using comparatively large rods of carefully purified carbon they found that the negative discharge to a small electrode in the neighbourhood of the rod diminished progressively as the gases were removed from the rod by continuous heating. The currents finally obtained at the highest temperatures were very much smaller than those recorded by other observers with carbon (see pp. 69 and 75). An application[1] of the considerations developed on p. 65, however, shows that the magnitude of the heating currents and the geometrical arrangement of the apparatus used by these authors were such that no electrons at all would be able to reach the electrode at the higher temperatures. Thus there is no difficulty in accounting for the smallness of the observed currents on the purely thermal theory of the emission. The only difficulty, which is present on any theory of the origin of the electrons, is to explain why the observed currents were not actually zero. The small currents can be accounted for[2] if it is supposed either that traces of gas present interfere with the motion of the electrons or that some of the electrons combine with uncharged molecules or atoms of the gas to form negative ions whose motion is almost unaffected by the magnetic field. Either of these assumptions would explain the fact that the observed currents are increased by the admission of traces of various gases. The relatively large effects produced by very small amounts of gas are in favour of the second hypothesis, which also explains the relative efficiency in this respect of the various gases tested. Another factor which would tend to make the currents observed in these experiments too small is the effect of the mutual repulsion of the electrons considered by Langmuir (see p. 61). Moreover, the results of the experiments are in complete disagreement with the results of experiments made with well-glowed-out carbon filaments by Deininger[3] in 1908, and of the more recent experiments of the writer and of Langmuir. In the last two cases the precautions described on p. 14 were taken in preparing the bulbs, and although it is not claimed that every trace of gas was got out of this very difficult substance, the conditions were much better in this respect than in the experiments of Pring and of Pring and Parker. The same claim can almost certainly be made for Deininger's work. In fact, it is quite impossible to attain good vacuum conditions with the large quantities of hot material used by Pring. Taking all the facts into consideration they appear to the writer to afford no support to the contention that the emission from carbon has anything whatever to do with chemical action. It may be that such a chemical effect exists, but its existence is not demonstrable, or even rendered probable, by the evidence which has been submitted.

[3] "Ann. der Physik," Vol. XXV, p. 285 (1908).

Thus there is no case in which it has been established with certainty that chemical action is the direct and immediate cause of an emission of *electrons*. The majority of chemical actions between solids and gases certainly do not give rise to electrical effects of this kind to any appreciable extent (see Chap. IX). The only case in which the evidence renders the occurrence of electron emission as a chemical effect probable is that of the alkali metals. The experiments of Haber and Just and of Fredenhagen do, on the whole, indicate a balance of probability in favour of a direct chemical effect in this case, although, in the judgment of the writer, they cannot be held to establish it with certainty.

The advocates of the chemical point of view have held that the emissions usually observed are due to actions between the hot metal and minute traces of residual gas and not to chemical actions on any considerable scale. In support of this it may be urged that, as the effect is a *purely* superficial one, a small quantity of gas will exert as large an effect as a greater amount, down to a certain limit. On the other hand, it cannot be said that a comparison of the specific effects of different gases lends any support to the chemical theories. In the case of platinum, the only gas which causes any considerable increase in the emission is hydrogen, and although there is probably some chemical combination in this case it certainly is not of a violent character. In the case of tungsten all gases which act chemically on the metal have been found to reduce the emission and not to increase it.

The difficulty, discussed on pp. 71 *et seq.*, of determining the precise values of the constants A and *b*, and the dependence generally of the emission on factors which are difficult to control and to specify, has been held to favour the view that these effects are caused by the interaction between the hot bodies and traces of gaseous contamination of uncertain composition. It would, however, seem more reasonable to attribute these features of the phenomenon to the fact that it is of an entirely superficial character and is very sensitive to changes in the nature or composition of the surfaces. For example, the admission of oxygen will coat the hot metal with a layer of oxide. If, as appears to be the case with calcium, the oxide is more active thermionically than the metal, the emission in presence of oxygen will exceed the normal value. If the oxide is inactive its presence will tend to prevent the electrons escaping from the metal and will thus reduce the emission. The effect of oxygen on tungsten is probably of this nature. Minute traces of gas would be sufficient to produce effects of this kind, and if the composition of the gas were uncertain and variable the effects would be correspondingly so. A similar difficulty arises in other superficial phenomena, such as the photoelectric effect, surface tension, and optical reflexion, although, as a rule, it is not so marked. This is on account of the extreme sensitiveness of the thermionic emission to small changes in the work required for an electron to escape. There is, in fact, no comprehensive body of evidence supporting the view that interaction with gases is an invariable and direct cause of thermionic emission; the evidence that gases act indirectly by modifying the quantity of the emission quite generally is of a much stronger character. In this connexion the close relationship between electron emission and contact potential difference, which is required on theoretical grounds, and the sensitiveness of both these phenomena to superficial contamination, should also be kept in mind.

Experiments made by the writer[1] have shown that the emission from tungsten in a good vacuum is a property of the element itself, and cannot be attributed to chemical or other secondary actions between the tungsten and traces of other contaminating material. The advantages of tungsten in investigations of this character have been alluded to already (p. 127). The tests were made with experimental tungsten lamps carrying a vertical filament of ductile tungsten which passed axially down a concentric cylindrical electrode of copper gauze or foil. The tungsten filaments were welded electrically in a hydrogen atmosphere to stout metal leads. These in turn were silver-soldered to platinum wires sealed into the glass container. The lead to the copper electrodes was sealed into the glass in the same way. The lamps were exhausted with a Gaede pump for several hours. During this time they were maintained at 550° to 570° C. by means of the vacuum furnace described in Chapter I. The duration of this exhaustion varied from 8 to 24 hours with different bulbs. It was continued until the apparent evolution of gas was very small and practically constant. This small final development of gas, which appeared to persist indefinitely, is believed to be due to the dissociation of the glass walls of the tube and to the diffusion through them of gases from the vacuum furnace which could only be exhausted to about 1 cm. pressure. The exhaustion was completed by means of liquid air and charcoal, the tungsten filament meanwhile being glowed out by means of an electric current at over 2200° C. Most of the tests were made after the furnace had been opened up and the lamps allowed to cool off. This treatment has been found completely to stop the emission, under the relatively slight heating caused by the radiation from the hot filament, of gases from the walls of the tubes and from the cold electrodes which had previously formed such a persistent source of difficulty in experiments with hot wires.

---

[1] "Phil. Mag.," Vol. XXVI, p. 345 (1913).

Although the filaments used were quite thin (about 0·007 cm. diameter), these lamps were found capable of being run so as to give thermionic currents of about 0·1 ampere for hours. Tests were made covering the following alternative possible causes of the emission :—

(1). That the emission is caused by the evolution of gas from the filaments.

In one experiment the tube was shut off by a mercury trap and the gases allowed to accumulate. The filament gave an electronic current of 0·50 ampere continuously for 30 minutes. The pressure of the gas which had accumulated was less than

10^{-7} mm. and was too small to measure. Taking into account the volume of the bulb, these figures show that for every molecule of gas evolved $2{\cdot}6 \times 10^8$ electrons were emitted. No conceivable process could cause so many electrons to arise from each gas molecule.

(2) That the emission is caused by chemical action or some other cause depending on impacts between the gas molecules and the filaments.

If for purposes of computation we consider the gas to be hydrogen, which is the most unfavourable assumption, since this gas makes most collisions, the data of the last experiment show that 15,000 electrons would have to arise every time a molecule impinged on the filament. This number is of course quite prohibitive. Moreover, in certain other experiments quite appreciable changes in the gas pressure caused no change in the emission.

(3) That the emission is a result of some process involving consumption of the tungsten.

In these experiments there is a loss of tungsten from the filament which is believed to be due to evaporation. The loss was determined by measuring the change in the resistance of the filament. At the same time the thermionic current was measured, giving the number of electrons emitted. In one experiment it was found that for each atom of tungsten lost 984,000 electrons were emitted. In this case the mass of the electrons emitted was *three times* the mass of tungsten lost. This experiment and others similar to it show conclusively that the emitted electrons must have flowed into the tungsten from outside points of the circuit.

(4) That the emission is caused by interaction with some condensible vapour which does not affect the McLeod gauge.

This explanation is cut out by the fact that the currents are not affected when the tube is cut off from the liquid air and charcoal and the hypothetical vapours allowed to accumulate.

These experiments have not been accepted as conclusive by Fredenhagen[1] and by Horton[2] on the ground that they still leave open the possibility that the emission is due to interaction with the tungsten of some substance present in the filaments. In regard to this suggestion it is to be remembered that the assumption of the presence of foreign substances in the filament is a pure hypothesis. It is very unlikely that any gaseous substance, and most substances are gaseous under these conditions, could remain in a thin filament kept at over 2200° C. in a vacuum of 10^{-6} mm. pressure for a long time. The behaviour of the filaments during the experiments is distinctly opposed to this suggestion. When they are first glowed out there is a considerable evolution of gas lasting for a few seconds, and after that nothing. When the filaments are sealed in a small closed tube and allowed to disintegrate through overrunning no gas is evolved. There is good evidence that the small quantities of gas which occasionally appear in experiments of this kind come from the walls of the tube and the relatively heavy parts of the metal electrodes owing to inadequate preliminary treatment. The only impurities which would seem to have any chance of remaining in the filaments during these experiments are the highly refractory elements such as molybdenum, tantalum, carbon, thorium, etc. Even these would be expected gradually to disappear, and *there is no evidence of any progressive change in the emission at constant temperature* with properly prepared tubes. In any event it is questionable whether their presence would help the chemical theory, which would then be reduced to the position of admitting the existence of an emission from alloys but not from the pure metals. That the emission cannot be attributed to the commoner gases is also shown conclusively by the experiments (see p. 125) of Langmuir, who found that they all reduced the emission, except the inert gases which left it unaltered.

---

[1] "Phys. Zeits.," Jahrg. 15, p. 19 (1914).

[2] "Phil. Trans., A.," Vol. CCXIV, p. 278 (1914).

These experiments with tungsten definitely exclude chemical action as the cause of the emission from this substance. Such, at least, is the considered judgment of the writer. Although equally searching tests have not been made with other materials, a general survey of the phenomena does not indicate any definite connexion with chemical action, certainly n the case of the refractory elements. This is supported by he results of Langmuir,[1] who finds that with tantalum, olybdenum, carbon, and platinum as well as tungsten, the mission is increased with progressive elimination of gaseous ontamination and corresponding freedom from liability to hemical action. There is, of course, no compelling reason o expect a purely thermal origin for the effects in all cases. t may be that in the case of the alkali metals such effects as ave been observed are due entirely or chiefly to chemical ction; but this has not yet been proved, certainly not with nything like the thoroughness of proof of the contrary proposition in the case of tungsten. If the emission is ever aused by chemical action we should expect this type of ffect to be exhibited by the alkali metals, where the reactions e much more vigorous than with the refractory elements, as shown by the very much greater heat liberation per gram quivalent.

There is another argument, to which great weight should e attached, which is definitely against a chemical origin of he effects exhibited by the refractory elements. We have een that the variation of the emission with temperature enables us to form an estimate of the energy change associated ith the liberation of one electron. We shall see in the next hapter that more direct methods are available for determining this quantity, both from the absorption of heat when electrons are emitted, and from the liberation of heat when electrons re absorbed. All three methods give consistent results, and how that the quantity in question is very considerable.

If we compare this heat change per gram equivalent of ectrons, with the heat liberated per gram equivalent in various chemical reactions, we find, in the case of tungsten or atinum, that it is about equal to the corresponding quantity r the most vigorous chemical actions known, such as the mbination of the alkali metals with the haloids, and is far reater than the heat of any known reaction of the elements nder consideration. Thus the rate of variation of the emission with temperature is right for the physical theory of the phenomena, but is wrong, so far as we can judge, for the chemical theory. It is desirable at present to restrict this argument to the more refractory elements which are less active chemically, as the thermionic data for the more electropositive elements cannot be considered to be known with sufficient definiteness.

July 15, 1875] NATURE 217

CHARCOAL VACUA *

(From a Correspondent.)

Prof. Dewar began his discourse by describing the different processes which have been adopted for obtaining very perfect vacua, and referred to a paper regarding this matter, read by Prof. Tait and himself before the Society last year.

By the ordinary air-pump the exhaustion can only be obtained to ⅛ of an inch, *i.e.* 1/240 of the ordinary pressure.

Regnault, in some of his experiments, after exhausting with the air-pump, boiled water, and when the water had evaporated, sealed the vessel, and then broke a flask inside containing sulphuric acid, and so the water vapour was absorbed.

Dr. Andrews' way is a revival of one due to Davy, viz. to fill and exhaust twice with carbonic acid after the pump exhaustion, and then by caustic potash to fix the CO_2 which is left.

Professors Tait and Dewar's method is to take advantage of the power charcoal has of condensing gases; while the exhaustion, by means of a mercury pump, is going on, the charcoal is kept heated; when the exhaustion has been carried as far as possible, the vessel is sealed, and as the charcoal cools, it condenses the very small residue of gas there may be present, and this can again be temporarily driven out by heating the charcoal. The test they have employed to gauge the perfection of their vacuum has been to see if it will allow an electric spark to pass. It is well known that at the ordinary atmospheric density it requires considerable tension for a spark to pass through air, and as the density diminishes, the spark passes more easily; but when a certain point is reached the difficulty again increases, and in a very perfect vacuum no spark passes at all. Two wires, ¼ inch apart, in one of Tait and Dewar's exhausted tubes would not allow a spark to pass, although a powerful coil was employed.

---

* By Professors Tait and Dewar. Paper read by Prof. Dewar before the R.S. of Edinburgh on Monday, July 12.

Prof. Dewar went on to say that the effect of light and heat had been tried by many experimenters, on magnets and delicately suspended bodies, and in the *Edinburgh New Philosophical Journal* for 1828 there is an interesting account of some experiments performed by Mark Watt on the same subject, with apparatus little differing in appearance from that now used by Mr. Crookes.

Recently Mr. Crookes has found some curious results which he seems to think are inexplicable. He found that the action of a beam of light on a delicately suspended glass fibre with a disc at each end was repulsion of the disc when the exhaustion was perfect, but attraction when at ordinary pressures. The discs were light bodies of pith or cork. One side of each was covered with lampblack, the other was white. The first thing to be noticed is that the blackened face is affected much sooner than the white face. Since there was attraction at one density and repulsion at another, it follows that at some intermediate density there is no action at all, and this neutral point depends among other things on the conductivity of the body and the nature of the residual gas.

It will be seen that for delicate action one essential is that the glass of the vessel be thin. The sensibility is also found to increase with the perfection of the vacuum.

The first fact ascertained is that the action follows the law of the inverse square of the distance, that which all radiation obeys. Thus, when the light was 3¾ inches from the beam, the reading was 110, zero 22, deflection 88; at 7½, reading 48, deflection 22, or only about ¼; and when at 11½, reading 33; and as zero changed, reading 33, deflection 9, or only about ⅑.

The next experiment was this. Professor Dewar interposed between the candle and the beam a substance opaque to heat rays. The candle was placed so as to give a large deflection, and then a vessel of ordinary glass was interposed, and the deflection decreased, and on filling the vessel with water, which is almost opaque to heat rays, there was no perceptible deflection left. This shows that when the heat rays are absorbed or prevented from reaching the disc, hardly any action takes place. A layer of water ¼ of an inch thick diminishes the amount of deflection to ⅛ part of the original.

Next a smoked piece of rock-salt was interposed, or a vessel filled with a substance transparent to heat but opaque to light, viz., a solution of iodine in bisulphide of carbon. The deflection was as before, large; on the empty screen being interposed a diminution followed, due to the non-transparency of the glass screen for heat. But when by means of the iodine solution the light rays were cut off there was hardly any further diminution in the deflection. This shows that the light rays may be taken away without any considerable diminution of the action.

Prof. Dewar then proceeded to show that the heating of the disc was the efficient cause of the action.

Two equal discs, one of rock-salt, the other of glass, were attached to the glass fibre. The rock-salt was inactive when the beam was thrown on it; the glass disc was active. The reason is evidently that the rock-salt is not heated, being transparent to heat, whereas the glass is opaque, absorbs the heat and is heated. Unless the shell of the receiver be thin, however, the selective action is very small, as the glass envelope absorbs much of the heat.

The back of the rock-salt disc was then coated with lampblack, and the beam sent through to the blackened side. Yet there would be attraction. The heat and light passes through the rock-salt and is absorbed by the lampblack at the surface of contact. The lampblack is heated up in consequence, but it is so bad a conductor that before this heat can be conducted through the thin coating of lampblack it is conducted through the rock-salt, heats it up, and the action is repulsion. If the lampblack were not so bad a conductor, all the lampblack would be first heated up and there would be repulsion at the other side, or apparent attraction. The subsequent action is due to the giving out heat unequally on the two sides.

The next modification was to substitute for the rock-salt clear sulphur and ordinary sulphur on the other. The peculiarity of clear sulphur is that when acted on by light it resumes the appearance of ordinary sulphur, with a disengagement of heat. A beam was thrown on this, and the effect was, as expected, attraction, the back being heated, and repulsion, there being attraction on the other side. The success of this experiment depends on the way in which the sulphur is transforming.

This suggested to the learned Professors an instrument for detecting the presence of very high violet rays. Have the transparent discs coated with white phosphorus, which is opaque to the ultra-violet rays. There would ensue a chemical action with disengagement of heat, and the result would be a motion of the discs. To show the sensitiveness of the apparatus, it may be stated that an ordinary lucifer-match held at a distance of 4 feet produced instant action, which was observed by means of a telescope. When ether was brought near there was attraction. The disc followed the ether about because there was radiation of heat from the disc. The action is clearly due to the infinitesimal heating of the discs. Reynolds suggested the action was due to the evaporation of some fluid on the surface of the discs. The recoil of the evaporating particles leaving the disc sent it back.

When the action takes place in ordinary pressures it is probably due to convection currents. The air in front of the disc is heated and ascends, there is a vacuum, and hence the disc advances. To understand the action that takes place when the exhaustion is more perfect, we must consider how much gas there is in the vessel. The capacity of the vessel is about a litre or 1000 cubic centimetres. But since we know that the exhaustion has reduced the density to $\frac{1}{4000000}$ of its original, the volume occupied by the residual gas at ordinary pressures would be that of a little bubble $\frac{1}{100}$ of an inch in diameter.

Sir Wm. Thomson, T. Clerk-Maxwell, and Clausius have shown that in a gas, at ordinary pressure, the mean or average path between two collisions is about $\frac{1}{10000}$ of a millimetre. When the pressure is reduced to $\frac{1}{4000000}$ the mean will be 400 millimetres, or about a foot and a half. What takes place is this. The particles of the gas are flying about in all directions, with a velocity which depends on the temperature. When they impinge on the heated disc their velocity is increased, they go off with a greater velocity than those which go off from the colder side, and hence there is a recoil of the disc. When the gas is at all dense the particles get a very short way before they are met by another and sent back, and so the velocity gets a common velocity before any visible action takes place. When the gas is rare the particles may get a long way off before they meet others, and so the action becomes perceptible.

In case of cooling they go away with diminished velocity and a negative recoil.

The author of the paper went on to show that the total mechanical action on a square centimetre of black surface derived from the radiation of a magnesium lamp, at a distance of 150 mill., did not exceed a continuous pressure of $\frac{1}{50}$ part of a milligramme, and that the total work done did not amount to the five-millionth part of the available energy received by the movable surfaces.

[Translation.]

TESTING METHODS OF PRODUCING HIGH VACUA.

BY KARL SCHEEL AND WILHELM HEUSE.

(Report from the Physical Technical Society.)

In a previous article we have shown that the vacuum gauge of McLeod may be used in producing the lowest pressure, when following certain precautions. In using this apparatus we have now quantitatively investigated the efficiency of the present-day methods for producing high vacua.

The receiver of the vacuum gauge of McLeod as used held 400 ccm.; its perfectly cylindrical capillaries had a diameter of 0.5 mm. The highest measurable pressure amounted to about 0.07 mm.; the instrument had a measuring range down to 0,00005 mm.

In addition to the vacuum gauge of McLeod, the air pumps to be tested were to evacuate a receiver holding a content of 6 liters. The connecting means between the vacuum gauge, receiver and the respective pump in use consisted of glass tubes having a width of at least 12 mm., and a length of about 1½ m. In front of the vacuum gauge a glass cock provided with a bore of about 3 mm., in width had been installed.

For the purpose of sufficiently drying the gas, vessels containing phosphoric anhydride had been introduced.

1. *Pump of Toepler.*

The receiver of the pump of Toepler, which prior to its use had carefully been cleaned and dried, held a content of 850 ccm. The test had been made in such a manner that one piston stroke was accomplished every four minutes, said stroke lasting about 2 minutes. The remaining 2 minutes were required for the equalization of the pressure.1)

(1) Remarks: According to a report just issued by M. Kundsen and relating to the transpiration of gases at low pressures, a formula supported by tests is given, said formula rendering it possible to calculate the rate of equalization in a tube system. In accordance therewith, for instance, the period of time required in order that a difference of pressure may be equalized to 1/100 of its amount between two tanks, each holding a content of 200 ccm., through a tube having a length of 1 meter, and a width of 6 mm., amounts approximately to 20 seconds. This period of time, as it occurs during our experiments with low pressure is independent of the pressure itself. We already arrived at similar results in connection with our tests relating to the diaphragm manometer as previously described. The continuation of such particular tests, which confirm the result even quantitatively, have become superfluous by the comprehensive observations of Kundsen.

TABLE I.

Pump of Toepler

Period of Time in Minutes.	Pressure in mm.	
0	0,0645	
12	0,0399	0,62
24	0,0254	0,64
36	0,0163	0,64
48	0,0107	0,65
60	0,00719	0,67
72	0,00459	0,64
84	0,00317	0,69
96	0,00210	0,66
108	0,00141	0,67
120	0,00093	0,66
132	0,00063	0,68
144	0,00048	0,76
156	0,00037	0,77
168	0,00025	0,68
180	0,00024	0,94
192	0,00015	0,62
204	0,00011	0,73
216	$0{,}00007_6$	0,71
228	—	
240	$0{,}00005_3$	
252	$0{,}00003_8$	
264	$0{,}00003_2$	0,71
276	$0{,}00002_5$	0,83
288	$0{,}00002_9$	0,77
300	$0{,}00002_2$	
312	$0{,}00002_4$	

After each of three piston strokes, thus every 12 minutes, a pressure measurement took place by using the manometer of McLeod. Table 1 shows the results of such series of measurements.

The last column of the table indicates the quotient between two consecutive pressure values. In the first part of the series, this quotient precisely corresponds to the ratio existing between the space to be evacuated and the receiver of the pump of Toepler, said quotient considerably increasing only towards the end of the series. The lowest obtainable pressure amounts to exactly 0,00002 mm.; this value coincides with a value of 0,000012 mm., found by Hagan.

2. *Mercury Jet Pump of Zehnder.*

The results of tests made by Zehnder, who obtained end pressures down to 0,001 mm., have been confirmed. Of course, the period of time required therefor had been considerably greater, amounting to several hours as compared with about 25 minutes in connection with a receiver of 600 ccm., by Zehnder.

3. *Pump of Gaede.*

For testing purposes the newest model of the pump of Gaede has been used, said pump having been provided with a porcelain drum encircled by a rubber valve ring, as required the pump had been filled up with 1500 ccm., of mercury, rotating at a rate of speed of 22 revolutions per minute.

In its second column, starting from a pressure of about 12 mm., and using the water air pump as preliminary pump, Table 2 indicates the decrease of the pressure according to the readings made at intervals of 5 minutes on the manometer of McLeod. The lowest pressure amounts to about 0,00006 mm., being obtained in about 45 minutes.

TABLE 2

Pump of Gaede

Time Minutes	Pressure in mm. Prepumped with

25	0,00016	$0,00001_8$
30	0,00011	$0,00001_2$
45	$0,00006_5$	$0,00001_3$
60	$0,00006_6$	$0,00001_1$

Much better results are produced when using a rapidly conveying oil pump instead of employing a water air pump. In the present instance the valveless pump of Gaede was used. The results obtained therewith have been indicated in the third column of Table 2, after 25 minutes. As the lowest pressure 0.00001 mm. was obtained.

In order to appreciate this value, attention is called to the fact that the entire system including the pump of Gaede continuously supplies a quantity of gas, which in 20 minutes would increase the pressure about 0,0001 mm. (approx. 0,0008 mm. after 24 hours).

4. *Mercury Pump of O. Roden S. Rosenthal.*

The pump is similar to a double-acting pump of Toepler. Its advantages as compared with the pump of Toepler, reside, on the one hand, in that it requires but a small amount of mercury (3,15 kg.), and on the other hand in that there is almost constantly a connection present between the receiver of the pump holding about ½ liter and the space to be evacuated. Another advantage to be considered is that the mercury does not come in contact with the open air during the operation, it being moved solely between vacuum and pre-vacuum, the use of hoses, being avoided. Finally, it is to be mentioned that the pump is to be constantly driven by a motor.

As expected, the pump rendered much better results, than could have been accomplished with a pump of Toepler provided with the same size of receiver. From Table 3, the progress of the vacuum within a space holding 6 liters, may be noted starting from a water air-pump-vacuum.

TABLE 3
Pump of O. Roden S. Rosenthal

135	$0{,}00002_0$	
145	$0{,}00002_0$	

if the receiver of the pump carries out 10 to 12 semi-piston strokes per minute. The end pressure is the same as it occurs in connection with the pump of Toepler, (0,00002 mm.).

5. *Carbon in Liquid Air.*

The carbon had been prepared from coconut shells by glowing same for 3/4 of an hour in a covered porcelain crucible exposed to a blast flame, previous to its being placed, in a glowing state, into a vacuum—"Exsikkator", where it remained until required for use. During the test the carbon (each 15 g.) remained in two cylindrical glass vessels I and II, which were fused to the system to be evacuated and which could be individually shut off from said system by means of cocks provided with large bores.

210		0,00026
270		0,00031

The tests were made in such a manner that, at first, both vessels containing the carbon were heated by using an interengaging drying pipe at the water pump. As soon as could be noted that the discharge of gas from the carbon stopped, then the heating was interrupted after disconnection from the water pump. After cooling of both carbons, carbon I was admitted to the fluid air acting upon the system.

The pressures as measured at intervals of 6 minutes have been indicated in Table 4. The decrease of pressure in the system at first takes place very rapidly, and, upon reaching 0, 001 mm., almost stops.

In continuation of the test carbon II had been extracted from gas, by heating into the vacuum of the system. Thereby the pressure increased to more than 0.1 mm., however, it was rapidly lowered to the former value of 0,001 mm., by the action of carbon I. Now, carbon I was disconnected, while carbon II was led into the fluid air; after 120 minutes, the lowest pressure of 0,00026 mm., had been reached, said result is supposed to be due to the yield of gases contained in the atmospheric air, which could not be absorbed by the carbon. If this non-absorbable portion was removed after the disconnection of the carbon from the receiver by using the pump of Gaede, then the gas reproduced by heating the carbon in a test analogous to the preceding one, had again been absorbed by carbon I up to a pressure of 0,0025, and by carbon II up to a pressure of 0,0001 mm.

Coconut Carbon in Fluid Air (Prepumped with a Pump of Gaede)

Time Minutes	Pressure in mm.
0	0,0059[illegible]
4	0,00380
10	0,00189
16	0,00062
22	0,00021
28	$0{,}00006_8$
34	$0{,}00002_1$
40	$0{,}00001_1$
52	$0{,}00001_1$
82	$0{,}00000_9$
112	$0{,}00000_7$

More favorable results were obtained within a short period of time with the coconut carbon in fluid air when starting out not from a water air-pump-vacuum, but from a lower pressure, say for instance 0,01 mm., as it can be produced by using the pump of Gaede in connection with the use of the water air pump as preliminary pump, even at large spaces, and with other pumps, at least as long as the receiver remains small. The Table 5 contains the results of such a series in which the starting vacuum 0,006 mm., had been produced by using a pump of Gaede. A pressure of 0,00001 mm., had been obtained after using of but one vessel filled with carbon after 40 minutes, apparently decreased slightly within the following hour.

This result is especially important because it shows that a vacuum of 0,00001 mm. may be produced and maintained for a longer period of time, without subjecting the apparatus to shocks, etc., as this is the case when operating mercury air pumps.

[TRANSLATION]

Treatise Dealing with a New Construction of the Mercury Pump of Toepler, Also Describing Some Experiments Made Therewith.

By ERNST BESSEL-HAGEN.

As to the various experiments which Mr. Crookes recently made regarding electric discharge and radiometric phenomena in strongly rarefied gases, he accomplished extraordinary evacuations, using the mercury air pump of Sprengel, improved by Ch. H. Ginningham (see Proc. Roy. Soc. 25 p. 396-402 Beibl. 1 p. 175-1877). According to the theory, this device permits of obtaining any degree of rarefaction provided that the mercury which continuously passes through the down pipe of the pump does not carry along any small quantity of air from the open atmosphere, discharging such air into the spaces to be rarefied. The chief drawback of the air pump of Sprengel, which will be obvious to everyone who had an opportunity of operating therewith, resides in that the rarefaction proceeds but slowly. Now, Mr. Ginningham has endeavored to lessen said drawback in that he built a pump based upon the principle of Sprengel, according to which he made use of three interconnected downpipes, instead of using but one; to these pipes the mercury being supplied from a common tank.

As far as its efficiency is concerned, the apparatus as constructed by Mr. Ginningham is, no doubt, thoroughly perfect, and Mr. Crookes has obtained with it the highest rarefactions as could possibly be had ever before. The apparatus, however, is complicated and fragile to such an extent that it became desirable to investigate whether it would not be possible to produce rarefactions just as high by using the extraordinarily ingenious and far simpler mercury air pump mentioned by Mr. Toepler, than it could be obtained with the one of Sprengel-Ginningham used by Mr. Crookes. It has been found that this not only had been the case, but also that it is even possible to obtain a considerably higher degree of rarefaction therewith (compare p. 138).

For the purpose of my experiments, I have slightly changed the original form of the air pump of Toepler, and refer to the main treatise as to its construction. Due to these changes, a pump has been produced in which, without using any cocks or the like, the connection with the recipient is established by glass and mercury only, whereby the limit up to which the rarefaction of the gas may be effected, is considerably increased than it would be the case in connection with the original construction, also its fragility is being materially decreased.

Description of the pump:

The arrangement and instalment of the pump may be seen from Table III, Figs. 7 and 8.

The glass tube A, the lower end of which is connected with the mercury tank Q by the thick-walled, black rubber hose S provided with a hemp lining, carries the air pump ball K on its upper end, from which ball branches the downwardly bent outlet tube B, being 2 mm. in width and 815 mm. in length, said outlet tube being bent upwardly opens into the tube C having a width of 13 mm. and a length of 250 mm.

The sections of the tube A located beyond and below the bulb K are connected with one another by a tube D of rather large diameter and bent in an obtuse angle, the purpose of said tube D being to avoid violent shocks which otherwise would occur upon the air passing from the recipient into the ball of the pump. At a point located below the lower end of the ball K, an ascending pipe open at its top and having a length of 110 cm. is molten to the tube D. By means of a suitable cork a pipe F serving as a mercury trough (made of a bottle, the bottom of which is burst off) is placed upon the ascending pipe E, mercury-tight (compare Table III, Figs. 7 and 8). In order to establish the connection between the pump and the recipient the apparatus is equipped with two long U-shaped pipes. One of these pipes (Table III, Fig. 7, designated G_1) carries the horizontal pipe H, to which the recipient (for instance as in our drawing a Geissler tube R) is molten, this being effected subsequent to the introduction of a small amount of phospheric anhydride into the drying ball M, and after the pipe I has been closed by melting. If now, upon opening the wooden member J, the free portion of the pipe G, be put over the ascending pipe E, until its lower end is sufficiently immersed in the mercury of the trough, and furthermore, if the pipe C and the mercury tank Q upon both of which a drying pipe containing calcium chloride is mounted, are filled with mercury, then the apparatus is ready for use (compare remark 1).

Remark 1: On publication of his sketch (Wied. Anm. 11, p. 522-1880) relative to a double acting, not yet manufactured mercury air pump, Mr. Neeson has changed his mercury air pump, as described in Wied. Anm. 3, p. 608, 1878, which, by the way, has been entirely unsatisfactory as to obtaining high rarefactions, in that he does away with the glass valves, substituting therefor, the construction of the outlet pipe of Toepler, as suggested by mr, and which advantages have been outlined on p. 433. In this manner, he has constructed an apparatus which, in its essential parts, covers the air pump of Toepler as hereintofore described. I wish to call attention to the fact that Mr. Florence Mueller (Berlin W. Kronenstr 71) for a period of three years, manufactures the air pump of Toepler according to my directions, i. e., a pump provided with a side pipe D and a pipe C directly sealed to the pump, these pumps are used by the Physical Institute to its full satisfaction.

The purpose of establishing a connection between the recipient and the air pump by putting over the one shank of the U—pipe G,—an arrangement, the construction of which is due to an identical suggestion made to me by Mr. Helmholtz—is to dispense with the application of a ground joint, yet to be in a position to easily connect the recipient with the pump or to disconnect it therefrom, also to use only glass and mercury as a closing means. If, namely, the recipient be evacuated by means of the pump, then the mercury rises from within the trough F into the space formed between the ascending pipe E and the shank or portion turned upside down of the U-shaped pipe G, however, it does not permit of any air from the open to pass into the recipient, since the length of the tube E as measured from the bottom of the trough F considerably exceeds that of the barometric mercury column.

One realizes that in this manner all faulty sources are excluded, which in connection with any other pumps equipped with ground cocks and lubricants must necessarily be present.

It is for this reason, that the present pump is extremely well adapted to be used in the manufacture of standard barometers, etc. For common use in laboratories, where, a rarefaction as high as possible is ordinarily not sought, and where fat vapors do not act destructive, it will of course be more preferable and convenient to establish the connection between the recipient and the pump by using suitable ground joint. For this purpose, the pump is provided with a second U-shaped connecting pipe G_2 (Table II, Fig. 8), which in these instances is intended to substitute that one just described above. Said second pipe G_2 also is provided with a drying ball M, adapted to receive phospheric anhydride, and equipped with a *"tubus"* and ground plug, to the upper portion of which is molten a ground joint N, into which a T-piece provided with two cocks may be inserted. Said T-piece serves as a connecting means with the recipient, and it also permits through cock W, of feeding air or gas either into the evacuated recipient or to the pump.

In order to again introduce air into the evacuated pump, without danger for the latter, on application of the first mentioned U-shaped connecting pipe, and subsequent to the experiment accomplished, it is advisable to pull out the tube I to be filled with phospheric anhydride into a very narrow capillary and to seal the latter subsequently. Then, all that is necessary in order to admit air after the experiment has been made is to open the point of the capillary tube. Of course, in order to accomplish this it is necessary that the tank Q previously be brought into its lowermost position so that the aperture of Pipe E leading to the ball K of the pump becomes free.

If it is desired to again introduce other gases into the recipients without resorting to a cock or the like, then it is necessary that an upright U-shaped pipe (compare Table [illegible], Fig. 8^a) located between the recipients and the vessels to be filled with such gases be used, the U-shaped pipe being 80 cm. in length. Said U-shaped pipe is furthermore provided with a smaller pipe molten thereto, which is connected with a mercury tank identical to that indicated at Q in Table III, Fig. 7. Any up- or downward movement of the tank forces the mercury to pass into the shanks or portions of the U-shaped pipe, or compels it to escape therefrom, thus it interrupts or restores the connection of the recipient with the gas filled spaces, as desired.

As far as the instalment of the pump is concerned, the entire pipe system is attached to a board in such a manner that the lower portion of the ball K is embraced by a sufficiently wide metallic strip which is filled up by gypsum, the remaining parts of the pipes are secured to the wood by means of screws. Upon the back of the board, a strutted board, horizontally arranged is secured to said first board so as to render it possible to fasten the pump to the experiment table by means of a screw. It is advisable to use this very way of installing the apparatus as the latter, in spite of its considerable weight, is not oscillating as it would be the case when using supports such as feet, etc. As can be seen from the figure a cork lined metallic clamp screw, at U, secured to the support serves for fixing the pipe H leading to the recipient and to the ground joint N respectively. The adjustable board fastened to the wooden support of the pump itself serves for the purpose of supporting the mercury vessel Q, when carrying the pump. In use the vessel is loosely held by the carrier T to be adjusted in any suitable height.

The manipulation of pumping is exceedingly simple, it merely consists of lifting and lowering the mercury vessel Q. I wish to briefly state this operation of the pump, taking into consideration the original treatise of Toepler: "If the mercury tank" is raised, then, as soon as the mercury within the pipe A rises until it reaches the point where pipe E opens into the recipient, the communication of the ball K and the recipient is interrupted by the mercury column rising in pipe E, whereas the air contained in the ball K is more and more compressed, until it escapes in the form of bubbles by passing through the mercury in the outlet pipe B C. If the tank Q be lifted to such an extent that the entire ball K is filled with mercury up to the mark O, and if there be no longer any escape of air bubbles at C, then the vessel Q is lowered, the mercury forthwith returns from the ball K and from the ascending pipe E, the opening of the latter becomes free, and the air contained in the recipient passes through the pipe D into the ball K. At the same time the mercury will rise in outlet pipe B from C, likewise from the trough F, in the space produced between the ascending pipe E and the pipe G, to a height which corresponds to the difference of the tension of the open air and of the air contained in the recipient. If the mercury drops from the bulb K until it reaches a point below the point of attachment of the pipe E, then the mercury vessel Q is again lifted, thus the connection between the ball K and the recipient is again interrupted by the mercury column rising within the ascending pipe, the tension of the air increases, the mercury column in B drops, until finally again a portion of the air previously contained in the recipient is removed to the open through the mercury located in the pipe C. It is noted that the air, if once removed from C, will never again return to the apparatus, as the pipe C is longer than is the height of the barometric mercury column. This kind of pumping is continued, until none or very few air bubbles escape at C. The outlet pipe B remains filled with air, the tension of which being equal to that of the atmosphere, augmented by the small mercury column, so that the mercury stands higher in C than in B. This amount of air filling the pipe B corresponds to that quantity having been left in the so-called "injurious" space of the ordinary air pumps. However, in order to eliminate same, it is necessary to lift the vessel Q slowly higher, until the mercury enters the outlet pipe B from the bulb K, thereby driving before it the air that has remained in the pipe, into the atmosphere. If now the mercury vessel be brought to its lowermost position, then a Toricelli-vacuum is formed above the mercury in the ball K, into which vacuum the air contained in the recipient is expanded as soon as the opening of the pipe E becomes free. The mercury flowing from tank Q to C during this pumping operation causes that the difference in height between the mercury level in the pipe C and the highest point of the tube B became smaller than is the length of the barometric mercury column, and, therefore, the atmospheric pressure automatically forces back the mercury which had been transferred to C, until the difference in height again becomes equal to the length of the barometric mercury column.

It is evident that the rarefaction may be carried on very far by repeatedly carrying out the process. In order that the air left in the pipe B be completely eliminated by the flowing mercury, the pipe B is given a suitable width (about 2 mm.), it also must terminate into the funnel-shaped pipe C (not hemispherical). This is important in case best possible rarefactions are to be obtained. If, for instance, as this is the case in connection with the original construction of the pump of Toepler, the pipe B (no matter whether straight or inclined) would be cut off below and immersed in a small upright cylinder partially filled with mercury, then the air bubble to be removed would obstinately adhere to the lower, acute edge of the outlet pipe B, is forced back by the mercury flowing back into the ball K, thereby rendering further evacuation slow, if not making it entirely impossible.

It has already been stated before that the final lifting of the tank Q is to be effected *slowly*, by means of which the flowing of the mercury from the ball K into the pipe B is effected so as to force the quantity of air left in said ball into the open. This is necessary, as otherwise the mercury jet entering the outlet pipe B at high rarefactions, during which the whole amount of air remaining in the ball K is finally compressed to a microscopic air bubble, would strike the mercury column in the pipe B so violently that the apparatus would be liable to be destroyed. For the reason, the support or carrier T of the mercury vessel Q is given only a restricted movement by using stop pins operating in one of the holes X and Y of the wooden column of the support either up- or downwards so that the mercury level Q in the highest and in the lowest position of the carrier T remains lower, i. e., almost equal to the length of the barometric mercury column, than the upper or lower discharge point of the pipe D. It is now possible without any danger to the pump, to always convey the mercury tank Q directly from its lowermost position into its highest position by means of the crank and the shaft secured to the support, the atmospheric pressure then rapidly removes the greater portion of the mercury from the vessel Q to the pump ball K, so that now, after this has been accomplished, the almost empty tank Q may be taken off the carrier T and be lifted so far that an overflow through the outlet pipe C is taken place. After the air has been carried off into the open by means of the mercury in the outlet pipe C, then the vessel Q is again attached to its carrier T where it is moved in its lowermost position by means of the crank.

Method of Measuring Pressure. A very marked advantage of the pump (to which Mr. Toepler made as yet no reference in his original description of the apparatus) consists in the fact that it permits the measurement of the pressure with every single stroke of the piston. (Mr. Toepler, in the Sitzungsber. der naturw. Ges. Isis in Dresden, 1877, p. 135, mentioned shortly). For this purpose there is fixed behind the tube B a scale which carries on one side a millimeter division, on the other side a volumetric division of tube B from 1/10 ccm. up, calculated from the intake point O forward. Furthermore, the common volume V of sphere K and the lateral tube D is determined by the mark O to the point of contact of tube E leading to the receptacle (recipient).

In order to make a measurement of pressure (this method of measuring pressure originated with Arago. See Regnault, relation des expériences. I. p. 491, Footnote, 1847) it is to be observed what is the position of the upper head of the mercury column in discharge pipe B:

(1) If reservoir Q is so far depressed that the pump ball K comes in contact with receptacle by means of tube E;

(2) When the quantity of gas contained in ball K is so far depressed by lifting mercury container Q as to fill with mercury the entire ball K to the point O, that is that the entire quantity of gas which before filled pump ball K

(3) only assumes now but a certain number v of decimal cubic centimeters in tube B.

If we name the volume of the gas V in the first case, x the pressure sought, v the volume of gas in the second case and h the number of millimeters constituting the difference of the two readings 1 and 2 of the position of the mercury column in tube B, then (if the cross section of tube B is small against that of C) manifestly this h is the increment of pressure which arose by compressing gas volume V to volume v, whereby its pressure must have risen to the magnitude (x + h). According to the Law of Mariotte there is found:

$$V.x = r(x + h)$$

and hence the sought for pressure obtaining in the receptacle

$$x = \frac{v}{V - v}.h$$

or, under the admissible supposition that V is very large in comparison with v:

$$x = \frac{v}{V}.h.$$

Data of the rarefactions obtainable by means of the Geissler, Toepler and Sprengel Air pumps.

I. Geissler Pump of the old construction (Wuellner, Exp.-Physik. 3 Edit. 1, p. 405, 1874, Mousson Physik 3rd Edit. 1, p. 178, 1879). In order to determine the limit of rarefaction for the Geissler mercury pump of the older construction, in which the doubly perforated cock by the well known method permits the reciprocal connection of the air-pump ball with the receptacle or direct with the atmosphere, tube described in Table III, Fig. 7, with H of the previously described Toepler Air Pump, was connected by means of a Kundt glass spring through soldering to the connecting pipe of the Geissler Pump (Kundt, Pogg. Footnote 155, p. 364 and 365, 1875). The first formed so to speak the receptacle for the latter, was exhausted by means of this and the rarefaction obtained after 20-25 strokes of the piston was measured by means of the Toepler Pump used only as pressure measuring device. The exhaustion was continued until there was no further indication of the diminution of the pressure.

The maximum of the rarefaction obtained was found to be 0.11 mm = 145 millionth of an atmosphere.

The reason why this pump does not permit of an even larger rarefaction degree is found in the fact that the mercury does not lie perfectly uniform on the glass walls when the gas contents of the air pump ball are driven out, whereby the wall of that part of the ball which is situated directly under the cock becomes invested with an air layer of the tension of one atmosphere, and furthermore chiefly in the fact that exactly in this space there arise unavoidably some small air bubbles which accordingly obstruct every further exhaustion of the quantity of air remaining in the so-called injurious space of the ordinary pump.

II. Geissler Pump of the new construction. The last-mentioned drawback was in the first place eliminated in a pump constructed in 1873 for the local institut and later on pretty generally by placing above the two-way cock an intermediate piece Z (see Table III, Fig. 9) closable by means of a special cock. In this construction the ball of the air pump never comes in direct contact with the atmosphere, and the rarefaction obtained by means of these pumps is incomparably higher.

Similarly to the above the Toepler Air pump was used as receptacle and pressure measuring appliance and exhausted with the Geissler pump.

The maximum rarefaction was found = 0.0082 mm,
after another 25 piston strokes x = 0.0085
25 0.0089
25 0.0086
25 0.0034
25 0.0084
average 0.0085 mm.

which numbers show that a further pumping would be of no use.

The pumps were now left in unaltered connection, in the first place in order to test the airtightness of all the cocks and slide pieces and then pumped a few times with the Toepler air pump, so that now the Geissler pump served as receptacle.

After pumping five times with the Toepler pump the pressure sank to 0.0075 mm. after a further pumping five times to 0.0064 mm.

It is recognized that the rarefaction here takes place much faster, which is all the more remarkable as the volume of the Geissler air pump ball was almost 800 ccm. that of the Toepler pump used only 474 ccm.

III. Toepler Pump (new form). In order to determine the limit of rarefaction of the Toepler pump of the construction before us, tube indicated with H in Table III, Fig. 7, was directly soldered, after phosphoric acid anhydride was poured into the dry ball through tube L and L was also thereupon closed by means of soldering. The rarefaction can be carried so far that there arises only a very small almost imperceptible depression of the mercury column in tube B, when the gas volume V in pump ball K is compressed to point O, that is to a certain volume v of the discharge pipe by means of suitable lifting of mercury receptacle Q. This depression had therefore to be measured by means of a microscope provided with a thread micrometer of long focal length. Before every reading, the mercury column was shaken by means of a slight tapping, so that the mercury head become freely settled. This is of course not entirely exact, but the following numerical data, obtained independently of one another, give us an idea how far this was the case, and regarding the absolute magnitude of the pressure increment h resulting from the diminution of volume. At the same time pressures p are also indicated alongside of the observation data required for their calculation: Marks V, v, h have the meaning indicated on p. 435.

V	v	h	Attained Rarefaction p
			mm.
615.4 ccm.	0.112 ccm.	0.075	0.000 014 = 1/54 millionth atmosph.
" "	0.112 "	0.084	0.000 015 = 1/50 " "
" "	0.104 "	0.054	0.000 009 = 1/84 " "
" "	0.112 "	0.078	0.000 014 = 1/54 " "
" "	0.112 "	0.044	0.000 008 = 1/95 " "
" "	0.104 "	0.060	0.000 010 = 1/76 " "

Average limit of rarefaction attained = 0.0000012 mm. corresponding to 1/63 millionth atmosphere, while

Mr. Crookes could reach only a rarefaction up to 0.000 046 mm = $\frac{1}{17}$ millionth of an atmosphere with the Sprengel-Ginningham pump. The reason why the Sprengel pump did not allow of the attainment of a still higher rarefaction was indicated at the beginning of this paper. According to a newspaper report (Rood, The New York Times, Nov. 19, 1880, p. 2, Sp. 3), Prof. Ogden N. Rood, of Columbia College in New York, succeeded in developing the rarefaction limit of the Sprengel Pump to $\frac{1}{64}$, and in one instance even to $\frac{1}{110}$ millionth atmosphere, by transmitting the mercury from a vessel which was itself exhausted into the drop tube of the air pump and thus made the taking along of the air bubbles impossible.

It is absolutely necessary that all the parts of the pump should be dry in order to attain such high rarefactions, and it is advisable to heat the tubes or vessels to be exhausted during the operation of exhaustion, during 24 hours if possible, to about 300° in the air bath, in order thus to separate the air film which adheres to the glass with extraordinary tenacity. If therefore exhausted vessels are desired to be closed by fusion under a given pressure, the respective part should be heated beforehand almost to the point of the softening of the glass and until an increase of pressure no longer takes place through further heating. The elimination of the air film may be obtained still more perfectly by sending electric discharges through the vessels to be exhausted during the pumping. Electricity needs the ponderable air particles as venicle in order to pass from one electrode to the other, and the result is that the air adhering to the glass wall is gradually loosened through the electric discharges, which may be directly proven by the increase of the pressure. The Geissler tube illustrated in Fig. 7, Table III, was exhausted down to 0.0009 mm., when during a certain time electric discharges were sent through it from an influence electrification machine; the gas glowed feebly, the glass wall was strongly phosphorescent. When the pressure was again measured in the usual way, it was found to be = 0.017 mm., hence had risen to almost double its previous magnitude. A part of the loosened air was again exhausted through further pumping, until the pressure was again almost 0.0009 mm. After electric discharges were again passed through for 5 minutes, the pressure became = 0.013 mm. That this increase of pressure could not be due to the rise of the temperature of the gas residue, may be proven simply by the fact that the volume of the Geissler tubes through which the electric sparks passed was about 300 cm., while that of the pump ball, dry vessel, etc., with which it was in constant connection, was over 500 cm. Whether this quantity of air originated from the electrodes or from the glass wall, could not be determined in advance; but that it did not originate only from the metal electrodes, may be seen from the fact that the pressure increase arose even in an electrodeless tube produced according to Gassiot's suggestion (Gassiot, Phil. Mag. 16, p. 308, 1858) on which two tinfoil layers were pasted on the outside, and which was made luminous only through the effect of induction. If the spark current is stopped and the tube is allowed to remain uninfluenced, the original pressure again returns gradually (after about 6 hours) even if not exactly, still at least approximately—whether through the absorption of the previously loosened air on the electrodes or the glass wall was not decided.

It was of special interest to verify whether under the highest attainable rarefactions the vacuum is really perfectly impervious for electric discharges or not. It is well known that the so-called Geissler absolute vacuum tubes, which according to Andrews' (Andrews, Phil. Mag. (4), 3, p. 104-108, 1852—Pogg. Ann. Footnote 88, p. 309-314, 1858) suggestion are first filled with carbonic acid, then exhausted and entirely cleared of their last vestige of gas through absorption by means of potassium hydrate, do not allow electric discharges to pass through between their wire-like electrodes brought to within 2 mm. of each other. Accordingly, the gas seems to be impervious to electric discharges at such high rarefactions. However, this is not at all the case. If fairly large metal plates are taken instead of the wirelike electrodes (the tube illustrated in Fig. 7, Table III, contained, besides the wirelike plates two other square, rolled up aluminum plates of a lateral length of 10 cm.), there still occurs electric passage in the interior of the tube under application of strong sparks, strengthened by means of Leyden jars, from an efficient influence machine, which is discernible through an intermittent, even though feeble phosphorescence of the glass wall, while at the same time the electricity discharges outside at the tube between the electrodes in loud crackling sparks. As a rule it is not possible to perform this experiment for a considerable time, for the tubes are almost regularly punctured by the sparks in the proximity of the one or the other electrode, which is then discernible on the immediately altered light phenomenon. This by itself very noteworthy phenomenon seems to be explicable by saying that the outer and inner wall of the Geissler tube charges itself from the electrodes similarly to a Leyden jar, until the tension difference becomes so high that the wall is broken through.

Of course, all the above gas pressure measurements indicate not the true, but only the partial pressure of the rarefied gas, for the pressure developed by the vapors of the mercury of the pump cannot be measured in the above way. Regnault gives the following values for the tension of the mercury vapor: (Regnault, Rel. d. Exper. 2, p. 520, 1862).

at 0° e = 0.0200 mm.
20° = 0.0372 mm.

These figures are somewhat too high as I found after a series of verifying experiments; the results of the latter, which I hope to be able to publish shortly, were found:

at 0° e = 0.0148 mm.
20° = 0.0201 mm.

It is never possible to get below this absolute pressure in the interior of the vessels to be exhausted, (Provided it is not possible to absorb the mercury vapors through some chemical means, e.g., metal gold, in a vessel containing only mercury vapors, with the vessel completely sealed on all sides) for with the use of mercury air pumps we have manifestly always to deal with spaces which contain saturated mercury vapors. It is surprising that the electric discharge phenomena, while the vessel is being exhausted, alter so strongly with the increasing gas rarefaction, although the true pressure—which is then chiefly represented through the tension of the mercury vapors—relatively hardly changes. According to this, the mercury vapor seems to have no importance in the electric discharges, it seems to be an insulator of electricity, similarly to water gas, which is an insulator, while running water is a conductor.

However, that we really have to do with spaces in all the parts connected with the mercury pump, which are filled with mercury vapor, may be proven with ease. All we need is to keep at a lower temperature for a considerable time any part of the wall of the spaces to be examined for this purpose, in order to obtain clearly discernible balls of condensed mercury.

Even if—as Mr. Crookes has done (Crookes, Phil. Trans. 2, p. 547, 1875)—the spaces to be exhausted are heated to red incandescence during the process of exhaustion and then sealed, even then upon cooling the apparatus to room temperature the partial pressure of the mercury vapor is still almost fifty times as high as that of the rarefied gases (Zoellner, Das Scalenphotometer, p. 37, 1879), and it must not be neglected of course in the considerations and calculations of the radiometric movements. On the other hand, the radiometric movements are unquestionably dependent on the pressure of the mercury vapor, as the two following experiments show.

(1) If a radiometer filled with air is exhausted almost to its limit, to which there is fused below a tube

of the length of about 15 cm., and at which the maximum sensitiveness arose for Mr. Crookes, so that, however, the latter has not yet been reached, and then it is caused to rotate by means of a candle and then the tube mentioned and sealed below is cooled by means of a cooling mixture, the pressure in the interior of the device is then diminished by the fact that the mercury vapors assume the correspondingly lower tension of the temperature of the cooling mixture, and as a result of this diminution of pressure the radiometer receives a higher rotational speed, which is of course not considerable, but which can still be measured with certainty. (Proportion of the number of rotations in one minute in an apparatus exhausted down to 0.04003, as 24:26, in other experiments 41:44).

(2) There was attached to a very thin, about 30 cm. long glass thread a mica plate 30 mm. wide and 70 mm. long, which was coated with soot on the respective halves of its front and back side, and which carried a round mirror α connected with it. The entire thing was enclosed in a wide tube illustrated in Fig. 10, Table III, which carried an about 10 mm. wide cooling tube, like the radiometer in the previous experiment, while at the upper end of the apparatus there was attached a tube, which latter was connected with tube H (Table III, Fig. 7) of the mercury pump by fusion. After the apparatus was protected against all influence of rays by covering it with a cylindrical double mantel, the rest position of the mica plate was determined and now the apparatus was exhausted as far as possible. The torsion apparatus still showed a turning even under the utmost attainable rarefaction (0.00001 mm.) as soon as said metal mantle was lifted off and the mica plate was exposed to the radiation of a light source. This deviation was observed by means of a telescope and scale, and it became appreciably less when the lower end of the apparatus was dipped into a cooling mixture as in the case of the above-mentioned experiment and thereby the tension of the mercury vapors was diminished. In or-

der to exclude the possibility of heat conduction in this as in the previous experiment, the upper part of the cooling tube was surrounded by a water vessel and the upper part of the apparatus was protected against rays from below by means of a double metal screen δ. As in the previously described experiment, the volume of the cooled part of the device was to be considered extremely small in comparison with the others, all the more so as both the radiometer and also the torsion apparatus was left in constant connection with the air pump ball during the experiment.

Experiments About Diffusibility of Hydrogen by Means of Continual Exhaustion.

It was mentioned above that the air film resting on the glass is eliminated only very slowly by means of continual exhaustion. It is always observed (even though all parts of the pump are completely tight) that there is a small increase of pressure, when the exhausted apparatuses are allowed to stand for a while. This phenomenon gave occasion to the suspicion that diffusion of the gas might have taken place through the glass itself, unless air seeps through the interjacent space between the glass and the mercury. However, this is not the case, as far as observable from the experiments to be presently described. Direct measurements of pressure could not of course decide this question, much less weighing attempts—as those made by Mr. Quincke (Quincke, Pogg. Footnote 160, p. 118, 1877), who wanted to prove egress of the gases by diffusion through the glass wall through the eventual diminution of the weight of a glass tube filled with hydrogen and with carbonic acid under high pressure (25 to 126 atmospheres). Even the most sensitive scale becomes a relatively insensitive instrument for this verification. The only experiment that gave promise of success seems to be the proof by means of the spectral analysis. For the purpose the tube combination illustrated in Table III, Fig. 11, was attached to the air pump. No. 1 is a spectral tube provided with aluminum electrodes, while in tubes II and III no electrodes are fused, there is attached to tube III a dry ball containing a somewhat concentrated sulphuric acid. Tubes Beta, Gamma, Delta, Epsilon, which connect the three spectral tubes among themselves and with the tube leading to the pump, are drawn out to thick-walled capillaries, in order that they can be easily fused off later on. The apparatus filled with atmospheric air was exhausted to a pressure of about 0.11 mm. (Maximum of the conductivity of the rarified air, corresponding to which the maximum of luminosity, See Morren, Compt. rendu 54, p. 735-737, 1862), thereupon fused off from the pump at Beta and then left hanging for five months, in the meantime several daily put into a slanting position, whereby the sulphuric acid again bedecked the walls of the dry ball and gradually absorbed every trace of water from the other three tubes. After this period the tubes was fused off first at epsilon, then at gamma, and delta. There were thus obtained three spectral tubes separated from one another, and filled with air of the same thickness and the same composition, of which tubes II and III were provided with rolled tinfoil coating for spectral analytic experiments. The spectral analytic examination showed that none of the tubes contained even a trace of hydrogen. Tubes I and II were next imbedded in another tube, which were later tightly drawn, then filled with hydrogen gas and sealed by fusing. Each of these spectral tubes was then surrounded with a hydrogen atmosphere, and when diffusion of the latter arose, the tubes I and II, investigated spectralanalytically, show another spectrum than that which was merely used as a compraison tube No. III, kept in a vessel filled with dry atmospheric air. However, after the lapse of almost one year, there was not shown in either of the tubes such a change, although the spectral analytic indication of hydrogen is, as is well known, very sharp.

It is also to be observed that the further divisions of the spectral tubes were constructed of thin-walled reagent glass.

ATTEST:

INVENTOR:

Thomas A. Edison

UNITED STATES PATENT OFFICE.

THOMAS A. EDISON, OF LLEWELLYN PARK, NEW JERSEY.

MANUFACTURE OF INCANDESCENT ELECTRIC LAMPS.

SPECIFICATION forming part of Letters Patent No. 411,019, dated September 17, 1889.

Application filed July 30, 1888. Serial No. 299,001. (No model.)

To all whom it may concern:

Be it known that I, THOMAS A. EDISON, of Llewellyn Park, in the county of Essex and State of New Jersey, have invented a new and useful Improvement in the Manufacture of Incandescent Electric Lamps, (Case No. 671,) of which the following is a specification.

The object of my invention is to produce high vacuums in the inclosing-globes of incandescing electric lamps, and especially to rid such globes of the watery vapor which adheres to the inner surface of the glass.

In carrying out my invention I connect with the exhaust-tube of the lamp a glass receptacle in which I have placed an absorbent of moisture, such as phosphoric anhydride, or a material like iron, which, when heated, decomposes water and takes up its oxygen. The lower end of this glass receptacle is drawn out into a hooked tube and sealed by the fusion of the glass, so that the lamp and receptacle form together an air-tight chamber. Upon the hooked end I hang a small coil of several turns of iron wire.

When phosphoric anhydride is used in the attached receptacle, I prefer to coat pieces of glass with that material and to place such pieces in the receptacle. I then place the lamp and receptacle in a suitable chamber and heat the same to from 600° to 800° Fahrenheit. The vapor is thus driven from the glass, and is absorbed by the phosphoric anhydride, from which it cannot afterward be removed even by heating. The whole is then attached to the Sprengel vacuum-pump, preferably by placing a rubber band covered with vaseline around the attached receptacle and inserting the same in the cup of the pump. I now apply a magnet outside the tube of the pump, and by its attraction for the iron wire hung on the glass hook I break off this hook, leaving an opening into the receptacle. The pump being now put in operation, the lamp is exhausted, any vapor which may have remained being absorbed by the material through which the air must pass. The lamp is preferably heated externally while it is being exhausted by means of a heating-lamp having a chimney surrounding the electric lamp. After the exhaustion is completed, the neck between the lamp and the attached receptacle is sealed off, there being a contraction in the neck for this purpose.

When particles of iron are placed in the attached receptacle, the lamp is placed in the chamber and heated as before to 600° or 800°, while the attached receptacle projects from said chamber and is separately heated to a much higher temperature, so that the iron is brought to a red heat and the vapor is thus decomposed, its oxygen combining with the heated iron, while its hydrogen remains to be drawn off by the pump after the end of the receptacle is broken off by the magnet, as already explained. Instead of this, a spiral of iron wire may be placed in the attached receptacle, or in another globe connected therewith, and provided with circuit-connections, so it may be brought to incandescence by an electric current, whereupon it acts to decompose the vapors in the same way as the iron particles above mentioned.

The accompanying drawings illustrate my invention. Figure 1 represents complete apparatus for exhausting the lamp; Fig. 2, a separate view of the lamp with attached receptacle; Fig. 3, a view of a modified arrangement as above described, and Fig. 4 a view of the completed lamp.

Referring first to Figs. 1 and 2, A is an incandescent electric lamp.

B is a glass chamber or receptacle forming a continuation of the exhaust-tube of the lamp, there being a contracted neck *a* between the lamp and the receptacle. This receptacle may contain pieces of glass covered with phosphoric anhydride or other moisture absorbent; or such absorbent may be placed therein by itself, or the chamber may contain particles of clean iron or other metal with which oxygen combines when the metal is heated.

As above explained, the lamp is placed in a chamber and heated to set free its moisture; or if the receptacle B contains iron it is heated separately from the lamp to a much higher temperature. The heating may be done in a furnace or in any other suitable way. It is not thought necessary to illustrate this step of the process, since it will be readily understood. The moisture being set free of the lamp, and having been either absorbed by the phosphoric anhydride or decomposed by the heated iron, which absorbs its oxygen and leaves its hydrogen, the lamp is attached to the Sprengel pump C, as above described, and as shown in *Fig.* 1, *b* being the rubber band covered with vaseline or similar material, so as to make an air-tight connection. An electro-magnet D is then brought close to the cup *c* of the pump and moved so that its attraction for the iron wire *d*, hung on the sealed hooked end *e* of the receptacle B, causes such hook to be broken off. The pump is then put in operation and the lamp is exhausted. Preferably during the process of exhaustion the electric lamp is heated by the flame of a heating-lamp E, from whose chimney a tube F, having an aperture for the exhaust-tube, extends, so as to surround the lamp. This heating drives off any moisture which may have remained in the lamp. If there is hydrogen in the globe, it is very readily removed by the pump. After the lamp is exhausted it is sealed off at *a*, and is then in the completed form shown in Fig. 4.

In the modification shown in Fig. 3 a chamber G, connected with a receptacle B, contains a spiral *d* of iron wire, which is heated to incandescence by an electric current while the lamp is being heated in the closed chamber, and also, if desired, while the lamp is being exhausted. It acts to decompose the moisture in the same way as the iron particles, as already explained.

What I claim is—

1. The herein-described method of removing moisture from the inclosing-globe of an incandescent electric lamp, which consists in hermetically sealing said globe to a sealed chamber containing a material capable of absorbing or decomposing such moisture and then externally heating said globe.

2. The herein-described method of exhausting an incandescent electric lamp, which consists in hermetically sealing the lamp to a sealed chamber containing a material capable of absorbing or decomposing such moisture, heating said lamp, and afterward withdrawing the air from said lamp.

3. The herein-described method of exhausting an incandescent electric lamp, which consists in hermetically sealing such lamp to a sealed chamber containing a material capable of absorbing or decomposing such moisture, heating the lamp, forming an opening in said receptacle, and withdrawing the air from the lamp through said opening.

4. The herein-described method of exhausting an incandescent electric lamp, which consists in hermetically sealing the lamp to a sealed chamber containing a material capable of absorbing or decomposing such moisture, heating the lamp, attaching the said receptacle to an air-exhausting apparatus, forming an opening in said receptacle, and exhausting the lamp by means of said apparatus.

5. The herein-described method of exhausting an incandescent electric lamp, which consists in hermetically sealing such lamp to a sealed chamber containing a material capable of absorbing or decomposing such moisture, heating the lamp, attaching said receptacle to an air-exhausting apparatus, forming an opening in said receptacle by the attraction of a magnet for a magnetic body attached to said receptacle, and exhausting the lamp by means of said apparatus.

6. The herein-described method of exhausting an incandescent electric lamp, which consists in hermetically sealing the lamp to a sealed chamber containing a material capable of absorbing or decomposing such moisture, heating the lamp, and then withdrawing the air from the lamp and at the same time heating it again.

7. The combination, with an incandescent electric - lamp globe, of a sealed receptacle hermetically sealed thereto containing a material capable of absorbing or decomposing moisture and having a magnetic body attached to it, substantially as and for the purpose set forth.

8. The combination, with an incandescent electric-lamp globe, of a receptacle hermetically sealed thereto containing a material capable of absorbing or decomposing moisture and having a sealed hooked end, and a coil of iron wire hung on said hooked end, substantially as and for the purpose set forth.

This specification signed and witnessed this 20th day of July, 1886.

Attorneys

UNITED STATES PATENT OFFICE.

ARTURO MALIGNANI, OF UDINE, ITALY.

PROCESS OF EVACUATING INCANDESCENT LAMPS.

SPECIFICATION forming part of Letters Patent No. 537,693, dated April 16, 1895.

Application filed August 18, 1894. Serial No. 520,593. (No specimens.) Patented in Italy January 7, 1894, XXVIII, 3,550, LXX, 46; in Austria March 16, 1894, No. 44,486; in Hungary May 5, 1894, No. 354, and in Belgium July 16, 1894, No. 110,854.

To all whom it may concern:

Be it known that I, ARTURO MALIGNANI, a subject of the King of Italy, and a resident of Udine, in the Kingdom of Italy, have invented a certain new and useful Improved Process for Evacuating Incandescent Lamps, of which the following is a full, clear, and exact description, and for which I have obtained a patent in Italy, dated January 7, 1894, Vol. XXVIII, No. 3,550, Att. LXX, No. 46; in Belgium, dated July 16, 1894, No. 110,854; in Austria, dated March 16, 1894, Reg. 44, Fol. 486, and in Hungary, dated May 5, 1894, No. 354.

The present invention consists of a process for evacuating incandescent lamps and bulbs.

Reference being had to the accompanying drawing, the bulb A is provided with a small glass tube T for the purpose of extracting the air and the gases therefrom as hereinafter specified. Substances, adapted under certain circumstances to generate gases or vapors, such as arsenic, sulphuric or iodine are then introduced into the interior of the bulb A advantageously at about the center of the tube T. The gases thus generated are intended to combine with the gases generated by the filament of the lamp when brought to incandescence and form a liquid or solid precipitation.

The most convenient method is to dissolve or dilute a powder in or with appropriate liquids, such as alcohol, essence of tremandra or the like in which case the same can be applied most easily. The lamp is then connected with a vacuum pump of any kind by means of the tube T and exhausted to the extent of about two millimeters of mercury. The vacuum having been obtained, the lower end of the tube is soldered up and the carbon filament is then brought to intensive incandescence, which has the effect of generating the gases contained therein. During this time the part containing the substance, is heated by suitable means such as a spirit lamp or the like, which causes the said substances to be transformed into gases or vapors. These latter then combine with the gases and vapors generated by the filament to form a solid or liquid precipitation, so that an almost perfect vacuum is obtained. The introduction of a small quantity of ether vapors or other hydrocarbonates into the lamp renders the combination of the above gases and vapors easier and more energetic and assists the production of the vacuum. After having obtained the vacuum it only remains to solder up the tube T at the lower part b of the bulb so that the latter can be removed and the lamp is ready for sale. These operations can be performed very quickly as it is possible to obtain a vacuum in from one to three minutes and even less, according to the nature of the filament, which varies. The quantity and nature of the gases generated by the filament vary also, so that it is necessary that the substances, the vapors of which are to be precipitated in a solid or liquid state, should be carefully chosen due regard being had to the nature of the filament and the proportion should be varied accordingly.

I claim as my invention—

1. A process for producing a vacuum in the bulbs of incandescent lamps consisting in first introducing into a tubular elongation of said bulb suitable substances capable of being gasified by heat and combining with the gases generated by the filament when brought to incandescence to form solid or liquid precipitations, then exhausting the said bulb by means of a pump and sealing the said tubular elongation up, then bringing the filament to intensive incandescence and simultaneously heating the substance in the elongation aforesaid and finally sealing off the said elongation in the manner and for the purpose substantially as described.

2. In a process for producing a vacuum in the bulbs of incandescent lamps consisting in first introducing into a tubular elongation of the bulb a substance or substances having the qualities specified, exhausting the bulb by means of a pump, sealing the said tubular elongation then bringing the filament to intensive incandescence and simultaneously heating the said substance or substances in the elongation and sealing off the said elongation, the application in the bulb of ethers or other suitable hydrocarbonates during the process in the manner and for the purpose substantially as described.

In witness whereof I have hereunto set my hand in presence of two witnesses.

UNITED STATES PATENT OFFICE.

ELMER F. DWYER, OF LYNN, MASSACHUSETTS.

PROCESS OF PRODUCING HIGH VACUUMS.

SPECIFICATION forming part of Letters Patent No. 596,654, dated January 4, 1898.

Application filed October 26, 1897. Serial No. 656,430. (No specimens.)

To all whom it may concern:

Be it known that I, ELMER F. DWYER, a citizen of the United States, residing at Lynn, in the county of Essex and Commonwealth of Massachusetts, have invented certain new and useful Improvements in Processes of Producing High Vacuums, of which the following is a description.

My present invention relates especially to a process for exhausting air and other gases from incandescent electric lamps or similar receptacles during their manufacture and repair; and its object is to render this operation speedy and with a minimum of attention required on the part of the operator, while the production of the high vacuum required in an incandescent lamp is assured, and discoloring of the lamp-bulb is largely reduced. In the past such lamps have been exhausted by mechanical pumps having cylinders and pistons, by mercury-pumps of the Geissler and Sprengel types and their modifications, by chemical processes involving the displacement or absorption of the gases contained in the lamp, or by combinations of these processes. A partial or incomplete vacuum, but one not carried sufficiently high to serve the purposes of the best grade of incandescent lamps, is readily obtained by a good mechanical or mercurial pump, but it is in the removal of the residual gases remaining after such exhaustion that the greatest difficulty is encountered, since that part removed by each stroke of the pump or by the successively-falling drops of mercury in the case of the Sprengel pump becomes continually smaller and smaller, being simply a certain fraction of the expanding remaining gases; and soon a limit is reached, which is, however, still below the desired vacuum, beyond which no further exhaustion by this means is possible. To carry the vacuum still higher, it has been a common practice to heat the lamp-bulb by either an external source of heat, such as a gas-flame, or by an electric current passed through the lamp-filament, or by both of these means combined, so as to expand the gases in the lamp, and also to drive off from the lamp-filament itself and its supports, more particularly the joint between the leading-in wires and the filament, which joint is usually made of some form of hydrocarbon paste, gases occluded therein, while continuing the pumping operation. It is possible to make commercial lamps in this way, and they have been so made for a number of years, but the process is prolonged and costly, and therefore to obtain greater rapidity and economy in this work the method has been practiced of placing a chemical substance in a space connected with the lamp, which gives off vapors or gas when heated, which vapors or gas mingle with or displace the gases remaining in the lamp, and the combined gases are afterward removed by continuing the pumping or by absorbing them by some other substance having a strong affinity therefor. For example, ammonia-gas has been introduced and absorbed by phosphoric anhydrid, or solids—such as mercury-vapor, the vapor of sodium, potassium, iodin, &c.—have been introduced, the pumping continued, and the residue allowed to condense in a cooled auxiliary vessel connected to the lamp during exhaustion. Arsenic has been proposed to be introduced as a vapor and is supposed to form a chemical combination with the residual gases of the lamp and go down as a solid deposit. Still further, it has been proposed to use a substance having in a large degree the power of absorbing gases, such as spongy platinum, which, being heated, gives off retained gases during the process of exhaustion and afterward occludes or takes up the residual gas when the heating has been discontinued and pumping stopped.

I also in my present invention employ a chemical to obtain the condition of highest vacuum, depending mainly on the displacement of the original gases by a gas evolved from the heated chemical, this substance having the property of evolving a condensable gas or vapor which, when the heating is discontinued, goes down as a solid upon the cooler portions of the receptacle and requiring quite a high temperature to be afterward again vaporized.

In my improved process, and according to the theory of action just alluded to, I aim to reduce the amount of this added gas or vapor, so as to limit the ultimate deposition of foreign substance upon the inner surface of the lamp-bulb after the pumping is stopped, and to this same end and for the further purpose of avoiding the necessity for skilled and close attention on the part of the operator I make the production of the added gas and the disengagement from the filament and its supports of occluded gases simultaneous and automatically so, or at least with such definite relation as to time as will give the best results with the minimum of attention required on the part of the operator and in the shortest time. By "best results" I refer to a lamp having the very high vacuum required in an incandescent lamp to insure a long life and one having the least possible or least permissible amount of foreign substance deposited as a film upon the inner surface of the lamp-bulb, which deposited film will in most cases tint the lamp.

I will now describe my process, reference also being made to the accompanying drawings, in which—

Figure 1 represents an ordinary incandescent lamp in its completed condition; and Figs. 2 and 3 are magnified representations of the leading-in wires, the joints, and portions of the lamp-filaments.

In Fig. 1, B is the lamp-bulb; S, the socket for attachment to a lamp-fixture; L^1 L^2, the leading-in wires; F, the lamp-filament, and J^1 J^2 the joints which unite the filament to the leading-in wires.

The same letters of reference are used in Figs. 2 and 3 for similar parts shown, J^1 being the joint between the filament and leading-in wire. This joint is usually, if not always, made of a carbon paste or hydrocarbon paste. It is from this joint that by far the larger portion of gases is evolved when it becomes heated, as by passing an electric current through the filament. In my improved process I mix with or place upon this hydrocarbon-paste joint J^1, Fig. 2, or apply to or paint upon the leading-in wire L^1, Fig. 3, a substance having the properties of amorphous phosphorus, which when heated gives off its vapor, such chemical being applied, of course, prior to the placing of the lamp upon the pumps. I then place the lamp in connection with any good air-pump, mechanical or mercurial, at its exhaust-passage, as at T, Fig. 1, and make the usual rough exhaustion. I then pass an electric current through the lamp-filament, preferably limiting the current at first, so as not to raise the filament to full incandescence, and continue the pumping. The heat from the filament first expands the gas remaining within the lamp-bulb, permitting its further removal by pumping. Gradually the heat is conducted back to the joints J and to the leading-in wires L, when upon an increase of current the disengagement of the occluded gases and the gases produced by the paste joint is partially effected, while the production or evolution of the condensable or displacing gas, as from phosphorus, begins, and then, lastly, the current passing is still further increased for a short time to or above that required for the normal operation of the lamp in use, when practically all of the occluded or retained gases are driven off from the joint, filament, and leading-in wires, while at the same time the vaporization of the phosphorus is completed, and the volume of gases now permits further pumping, the excess gas being that derived or obtained from the phosphorus. The lamp is now sealed off. The gas now remaining in the lamp is mainly that which has been purposely added, say phosphorus-vapor; but as the lamp cools this gas or vapor condenses upon the cooler portions or goes down as a solid, as an extremely-attenuated film upon the inner side of the lamp-bulb, and will not again arise as a gas unless again subjected to a temperature as high as that which produced it. Having by trial determined quite accurately just what minimum amount of condensable gas is required to be produced in this way to perfect the vacuum to the stage desired, I am enabled to limit the deposit formed by its condensation upon the bulb-surface to the greatest extent and therefore to produce a superior lamp, while at the same time the processes of expanding the free gases in the lamp, driving off the occluded and retained gases from the joints, &c., and evolving the condensable gas follow naturally in their proper order to insure the best results with a minimum of skilled attention and in a very short time. The operator soon learns by simply noting the color within the lamp during exhaustion when to seal it off, and I find in the practice of my invention that I am actually enabled to greatly facilitate the process of exhaustion, so as to produce a greater number of lamps in a given time with less labor and giving a superior product as compared with the processes hitherto known or used. I show no particular form of pump or its connection to the lamp, these things being so well understood.

It is understood, of course, that an external source of heat may be employed for assisting in expanding the gas within the lamp during the pumping operation; but it is evident that such heating has no particular use in producing the condensable or displacing gas, since the source of the latter is far removed from the externally-applied heat. Such external heating is mainly useful in driving off gas from the inner surface of the bulb and preventing predeposition of the condensable gas on the bulb-surface.

Besides phosphorus I have used with greater or less success iodin and ammonium-cuprous chlorid. In general it suffices to employ a substance which will, when sufficiently heated, give off a gas capable of subsequent condensation; but such substance must not again be able to be vaporized by the heat of the lamp in normal operation. I prefer phosphorus to other materials.

Having thus described my invention, what I claim is—

1. The process of producing high vacuums consisting in, removing the main portion of the gases contained within the receptacle to be exhausted by pumping, heating the remaining gas while continuing the pumping, driving off occluded gases and producing or evolving a condensable or displacing gas by an electric current passed through a circuit within said receptacle, and finally sealing said receptacle.

2. The process of exhausting incandescent lamps which consists in, removing the main portion of the gases contained within the lamp by pumping, heating the remaining gases while continuing the pumping, passing an electric current through the lamp-filament whereby occluded or retained gases are disengaged while a condensable or displacing gas is evolved from a suitable substance previously applied in the lamp while still continuing the pumping, and, finally, sealing off the lamp.

3. The process of exhausting incandescent lamps consisting in, removing the bulk of the original gas by pumping, further expanding by heat the remaining gas and continuing the pumping, passing an electric current through the lamp-filament and its connections for disengaging occluded or retained gases therefrom and vaporizing phosphorus previously applied to said connections while continuing the pumping, and then, finally, sealing off the lamp, substantially as described.

4. As an improvement in processes for exhausting incandescent lamps, the method of producing the higher states of vacuums consisting in simultaneously disengaging the occluded or retained gases in the lamp-filament and its connections and producing or evolving a condensable or displacing gas from a suitable substance, such as phosphorus, carried by the filament-supports, by passing an electric current through the lamp during the operation of pumping, and afterward sealing the lamp to perfect the vacuum, substantially as described.

In witness whereof I have hereunto set my hand this 23d day of June, 1897.

8 AMERICAN ELECTRICIAN [Vol. VIII, No. 1

Crookes Tubes and Experiments With Roetgen Rays.

BY THOS. DUNCAN.

After using a Crookes tube a number of times it was observed that it required a greater electromotive force to operate it. This phenomenon has been noticed by several experimenters with Crookes tubes recently, but has been known for years to incandescent lamp makers.

If the vacuum of an incandescent lamp be tested by means of a spark coil when first made, and is found to show a luminescence inside, after being put in circuit and used for a month or so, it will be found upon trying it again with the spark coil, that little or no luminescence will take place with the original pressure or spark length. The writer has even found this to take place when a new lamp is subjected several times to a voltage double of that for which it was designed. The duration of contact must be very short or as nearly instantaneous as possible, not only to protect the filament, but also to prevent the interior of the bulb from being blackened.

I have also prepared lamps in this way for comparison with other makes, when showing intending purchasers the difference between the vacuum obtained in the lamps I represented and those sold by other makers. It undoubtedly shows that there are tricks in all trades.

The theory I always entertained regarding this increase in the rarefaction of the lamp was, that when incandescence takes place, the remaining air combines with the vaporized carbon particles or molecules that are undoubtedly thrown off from the filament, and is precipitated as a solid upon the interior surface of the receiver or bulb.

How far this theory involving chemical change with resulting precipitation can be applied in the case of Crookes tubes, I am unable to say, but would be inclined to think, as Prof. Elihu Thompson has suggested, that the improvement in the vacuum of the Crookes tube is due to the carriage of metallic aluminum or other metal forming the electrodes, to the sides or interior walls of the bulb, the residual gas being absorbed in so doing.

The success attending the production of good skiagraphs depends more upon the degree of rarefaction of the tube than anything else, and can be verified by any one who has had the misfortune of trying to obtain Röntgen rays from domestic tubes, or those made by makers of incandescent lamps.

It is possible that good Crookes tubes will be turned out upon the market by lamp makers, but it is to be regretted that some of these have been making and selling for the past month or two tubes that are as unfitted for the purpose intended, as their makers are to represent Professor Crookes in a mental capacity.

I have tried eight Crookes tubes made by four different incandescent lamp companies, but with only one tube could I obtain any good results, the vacuum in the other seven being so low and poor that it was useless to experiment with them. They did not seem to have any better vacuum than that shown by an ordinary incandescent lamp. The one tube which bore all the characteristics of a genuine Crookes tube was made by a St. Louis Company, and if all their lamps are exhausted in as thorough a manner as exhibited by this tube, they must undoubtedly receive credit for it.

There seems to be one thing certain, and that is, if any one undertakes to make Crookes tubes for skiagraphing through opaque matter, they will have to improve upon the ordinary practice and methods employed in exhausting lamps.

The very first step to be taken is to see that the pump is as clean and dry as it is possible and practical to make it. This may partially be accomplished by preventing moisture from entering either the mercury or the high vacuum chambers (mechanical or automatic Geissler pump), by causing the outside air which enters the mercury chamber at every operation of the pump, to pass through granulated calcium chloride, and interposing between the high vacuum chamber and the bulb to be exhausted, some anhydrous phosphoric acid, which has a great affinity for moisture. In the latter precautions the introduction of the anhydrous phosphoric acid prevents any moisture that may be contained in the bulb to be exhausted from passing down into the high vacuum chamber and coming in contact with the mercury. It must be remembered however that the anhydrous acid must be renewed often and not allowed to form a surface film or crust on top, when it is useless.

The foregoing suggestions are well known and understood by makers of incandescent lamps, so are given more with the view of assisting and aiding the casual reader who may not be so well informed or initiated into the precautions necessary for the production of high vacua.

If an incandescent lamp be exhausted until no air can be seen escaping through the valves of the pump, and the filament then incandesced, considerable quantities of air will be expelled at each operation of the pump, thereby showing that this air has been occluded in the pores of the carbon filament, and could not have been gotten rid of without heating the filament and driving the air out into the vacuous space surrounding it.

This heating also assists in drawing off the air which clings or adheres against the glass upon the inside of the bulb. Therefore in exhausting Crookes tubes, I should think that it would be good practice to smoke the bulb thoroughly upon the outside, then set an oil lamp or other source of heat under it, at the same time covering it over with an asbestos hood also smoked upon the inside, in order to concentrate the heat and distribute it as evenly and efficiently as is possible. This would help to remove the air from the inner surface of the bulb.

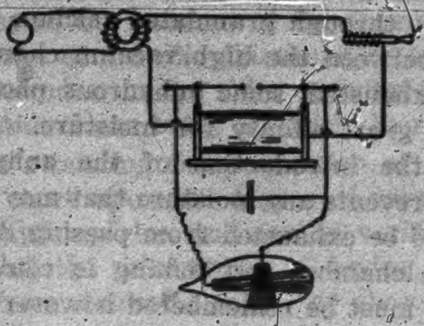

FIG. 1.

If the electrodes are made from aluminum or other porous metal, the secondary terminals from a spark coil can be applied to them, and set in operation in a similar manner to that in which the tube is to be used afterwards. This can not help but be a ready and satisfactory means of eliminating the air occluded within the electrodes.

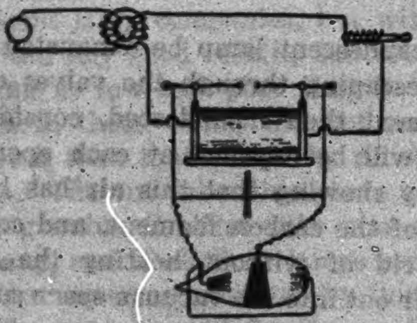

FIG. 2.

When we consider that mercury evaporates so readily even at ordinary temperatures, it might be admitted that a certain amount of mercurial vapor gains admission to the bulb, but even this may be prevented

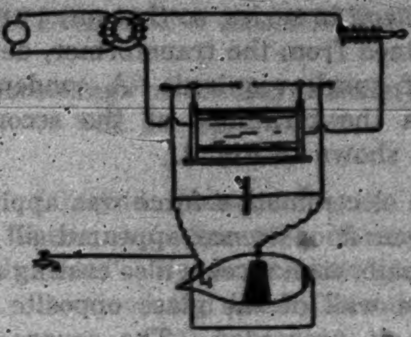

FIG. 3.

by interposing in the tube connecting the high vacuum chamber and the bulb being exhausted, a small quantity of iodine (next to the high vacuum chamber) which absorbs the mercury vapor, then some sulphur which in turn absorbs any vapors given off by the iodine, and lastly powdered silver, which completely absorbs any sulphurous vapor that may be evolved. This method of getting rid of the mercurial vapor has been employed by Professor Crookes himself, in connection with measuring the degree of rarefaction obtained with a Macleod gauge.

While experimenting with a Crookes tube, I noticed that a cathode stream was thrown off from both electrodes, due to the current used being an alternating one. With the object of trying to suppress one of them and increase the density of stream from the other, I tried the following experiments, which may prove of some interest to those experimenting in the production of Röntgen rays.

The current employed was the ordinary high frequency alternating current, making about 16,800 per minute, corresponding to a frequency of 140 periods per second.

The induction coil was capable of giving sparks up to eight inches; the primary was supplied from the secondary on a one hundred volt transformer, and had an inductance coil in series, so that any current strength could be obtained from the transformer, depending upon the length of spark required. A condenser was employed across the terminals of the secondary of the spark coil, as shown in Fig. 1.

When an electromotive force was applied, the usual yellowish green fluorescence appeared all over the interior of the bulb, each stream also casting a dark square spot upon the wall of the glass opposite the electrode from whence it proceeded. The square form of the dark spot was due to the electrode having a square surface.

Upon applying an external electrode of tinfoil, about the size of a silver dollar, to the end opposite the electrode whose cathode stream was thrown out horizontally, or across the greatest length of the tube, and then connecting with the electrode, it appeared to throw off a counter stream which perceptibly diminished the density of the stream from the inner or opposite electrode. This was also accompanied by a reduction in the fluorescence at the ends of the tube, and by an increase of the stream thrown off by the remaining or upper electrode, which in turn produced a marked increase in the fluorescence upon the opposite side of the tube. This arrangement is shown in Fig. 2.

When the hand was brought in contact with either or both of these end electrodes, the respective streams of cathode rays and resulting fluorescence were again reduced to a very marked degree, with an accompaning increase in the stream thrown off by the upper electrode.

This last result naturally suggested grounding the end electrodes, which was done by connecting to a water pipe; the experiment was then complete, the upper electrode throwing off a very strong and dense beam of cathode rays, causing the opposite wall to be very bright with fluorescent light, while the two other electrodes were as inactive looking as if they were not present at all. This arrangement is shown in Fig. 3.

Proceedings of the Royal Society A,
Vol. 64, pp. 231-238.

"Application of Liquid Hydrogen to the Production of High Vacua, together with their Spectroscopic Examination." By JAMES DEWAR, M.A., LL.D., F.R.S. Received and Read December 15, 1898.

As an illustration of the extraordinary power of the new cooling agent—liquid hydrogen, the extreme rapidity with which high vacua can be produced by its use is, perhaps, one of the most striking. The absolute boiling points of hydrogen, oxygen, and chlorine are respectively 35°, 90° and 240°, in other words oxygen boils at a temperature two and a half times higher than liquid hydrogen, and liquid chlorine similarly at two and a half times that of liquid oxygen. From this we infer that liquid hydrogen as a cooling agent ought to be relative to liquid air as effective as the latter is compared to that of liquid chlorine. Now chlorine at the temperature of boiling oxygen is a hard solid, some 80° below its melting point, and in this condition has an excessively feeble vapour pressure. When liquid hydrogen freezes air out of a sealed tube by immersing the end in the liquid, it is to be inferred that no measurable pressure of air ought to be left in the vessel. If we apply Van der Waal's law of corresponding temperatures to the case of hydrogen, the above inference is made unimpeachable. An approach to some knowledge of what the tension of air must be about the boiling point of hydrogen can be attained by extrapolating the vapour pressure curves of oxygen and nitrogen. Taking the following range of boiling point temperatures for nitrogen and oxygen, viz., from the critical point to the boiling point under diminished pressure, two Willard Gibbs formulæ were calculated, with the following results:—

Nitrogen	Temp. abs.	127°	78.6°	59°
	Pressure in mm.	25,900	740	26

Nitrogen. $\log_{10} p = 11.5561 - \frac{400.02}{T} - 1.8980 \log_{10} T$ . . (1).

Oxygen				
	Temp. abs.	154°	90.3°	61.3°
	Pressure in mm.	37,592	740	7.5

Oxygen. $\log_{10}p=9.4699-\frac{422.22}{T}-0.9843\log_{10}T$ . . (2).

Another Gibbs formula was calculated, taking Estreicher's values for the vapour pressure of liquid oxygen below its boiling point, viz.:—

Temp. abs.	91.44°	78.1°	62.8°
Pressure in mm.	743.8	141.8	7.5

Oxygen. $\log_{10}p=16.0670-\frac{524.72}{T}-3.8024\log_{10}T$ . . (3).

We deduce from these formulæ the following vapour pressures at the temperature of boiling hydrogen:—

(1) Nitrogen ...... 0.0015 Pressure in mm., 35° abs.
(2) Oxygen .... 0.000076 do.
(3) " .... 0.000016 do.

The results of calculation, taking the formulæ for the widest range of pressures, viz., (1) and (2), may probably be the surest, but in any case those values must be taken as a *maximum*, seeing they refer to the liquid state, while both oxygen and nitrogen, at the temperature of 35° absolute, are hard solids, and must therefore have dropped to lower tensions than that of the extrapolated liquid vapour pressure curves. It is curious to note that at this low temperature the theoretical ratio of the tensions of nitrogen and oxygen is as 20 to 1. Direct measurements of the vapour pressure of nitrogen at the melting point, or 60° absolute, gave the value of 26 mm., and a ratio of the tensions of nitrogen to oxygen of 6 to 1, whereas from the curves the value ought to be 6.7 to 1. Olszewski gives the tension of nitrogen at —214° as 60 mm., and as at this temperature the oxygen tension is 3.8 mm., the ratio of the saturated pressures of the two gases at the melting point of nitrogen would be as 16 to 1, which is far too high. Probably the oxygen value will be nearest the truth, seeing it has the lowest melting point. The tension is about a ten millionth of an atmosphere. In the case of nitrogen, the maximum theoretical pressure would be one five-hundred-thousandth of an atmosphere. It is safe to infer that the vacuum left after liquefying the air out of a vessel by means of liquid hydrogen cannot exceed the millionth part of the atmospheric pressure, exclusive of the pressure resulting from any incondensable material other than nitrogen and oxygen. This is just about the pressure of the vapour of mercury at the ordinary temperature in the Torricellian vacuum, so that as good an exhaustion ought to result as can be got by boiling out a space with mercury. There is another way in which the question may be put. Assuming the molecular latent heats are approximately proportioned to the absolute boiling points, then we can, from a comparison with the oxygen value, deduce that of hydrogen, and thereby get the constants in a two-term formula for the vapour pressures. For pressures below an atmosphere, the following formulæ were deduced:—

$$\text{Oxygen} \;\ldots\; \log p = 7.2058 - \frac{392.6}{T}\,\text{mm.} \;\ldots\; (4).$$

$$\text{Hydrogen} \;..\; \log p = 7.2428 - \frac{152.7}{T}\,\text{mm.} \;\ldots\; (5).$$

From these expressions it follows that at its boiling point, or 35° absolute, hydrogen has 7/852000 times the pressure of oxygen, or the latter pressure is about the eight millionth of an atmosphere. A similar formula, calculated from the critical and boiling point data, gives substantially the same order of quantities. Formula (4) for oxygen tensions must be fairly accurate, seeing it gives a theoretical latent heat of about 56 units per gram of liquid evaporating at the boiling point, whereas direct determinations result in 55 units. To test this inference, the following plan of experimenting was adopted:—Ordinary shaped vacuum tubes, like A, B, used for the spectroscopic examination of gases, with and without electrodes (figs. 1 and 2), having a capacity ranging from 15 to 25 c.c., had pieces of quill tubing about a foot long sealed on. The tubes were contracted at D to about 1 mm., so that they could be sealed off with rapidity.

The end C sometimes terminated in a small bulb (fig. 3), in order to give increased cooling surface, and when necessary, to allow many times the volume of air in A, B, to enter and be condensed with the object of accumulating any incondensable residuum.

Fig. 1.

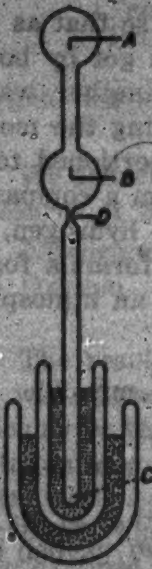

Fig. 2.

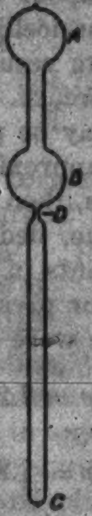

Fig. 3.

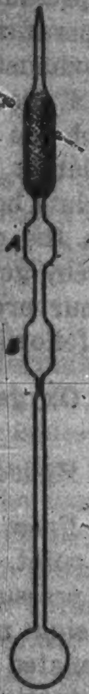

The tubes were filled with air, oxygen, and nitrogen at the atmospheric pressure. The liquid hydrogen collected in the vacuum vessel, immersed in another similar vessel full of liquid air, being ready, the end C was dipped in the liquid for a little over a minute, and the tube AB sealed off at D, so that on removal from the hydrogen bath the solid air might melt and distil off without generating any pressure. On attempting to pass the spark through vacuum tubes prepared in this manner, their excellent exhaustion was revealed by great resistance to the passage of the discharge, and the high phosphorescence of the glass. Two tubes, kindly prepared by Sir William Crookes with platinum electrodes that he had previously sparked to remove gases and impurities on the glass before filling with dry air, gave, when treated in the manner described, such high vacua that the tubes had to be heated in order to get any spark to pass. Thus it is proved that the tension of solid nitrogen and oxygen at the temperature of boiling hydrogen is below the millionth of an atmosphere, seeing there is less difficulty in getting a discharge to pass in tubes exhausted to this extent. In order to get some definite idea of the limit of the exhaustion produced, two tubes, such as have been described as suitable for the liquid hydrogen experiments, might be joined together and filled with oxygen or nitrogen at atmospheric pressure, and simultaneously exhausted with the mercural pump to a small fraction of an atmosphere, and then sealed off from the pump and each other. One of these two identical tubes could then be subjected to the hydrogen cooling, following the directions already given, and the two vacuum tubes now compared. If there was a marked difference in resistance to the passage of the discharge in the frozen tube, then something must have condensed, and by a few tentative trials a limit might be reached when the initial exhaustion was unaffected by the hydrogen cooling. Such experiments have not yet been made. The presence of any vapour of mercury would require to be carefully eliminated, otherwise the method would not be satisfactory. Tubes that are prepared without taking special precautions to exclude organic matter and water from the glass, deteriorate, especially with electrodeless tubes after the discharge has taken place for some time.

The rapidity with which the vacua are attained is such as theory would suggest; assuming a hole of a square millimetre in section through which the air rushes into the condenser, and that a velocity of current between 600 and 700 feet a second is attained, then a vessel of 20 c.c. capacity could be reduced in pressure in 1 second to $1/10$ of the initial pressure, and if the same rate is continued at the end of 60 seconds to $(1/10)^{60}$. Sir George Stokes has been good enough to consider the problem and writes as follows:—

"Let V be the volume of the vessel, A the area of an aperture by which the air is conceived as rushing out with the velocity v, ρ the density of the air in the vessel at the time t, D the initial density, that is, the atmospheric density.

"Then, according to our hypothesis, $Av.dt$ is the volume of air, and, therefore, $Av\rho.dt$, the mass of air, which rushes out in the time dt. But this equals the loss of mass of air in the vessel during the time dt, and, therefore,

$$Av\rho.dt = -Vd\rho,$$

a differential equation of which the integral is

$$\rho = D e^{-Avt/v}.$$

"Suppose now V to be 20 c.c., or 20,000 c.mm., A to be the area of a circle of 1 or 2 mm. diameter, say 2 sq. mm., v to be 333 m., or 333,000 mm., t (in seconds) to be 60; then

$$\log_e \frac{D}{\rho} = \frac{2 \times 333{,}000 \times 60}{20{,}000} = 1998,$$

$$\frac{D}{\rho} = 5254 \times 10^{484}.$$

"This would give a density of almost inconceivable smallness. Doubtless the supposition made above as to the rate of discharge is very wide of the mark, being much too great. If the velocity of rushing is about half the velocity of sound, the ratio of densities would become 72×10^{217}. If so it is satisfactory to find that the mathematical following out of the hypothesis leads to a density of the residual air in the vessel which is enormously below what suffices to account for the observed result." A practical mode of rapidly attaining a high vacuum in any vessel is to displace the air with carbonic or sulphurous acid, either at the atmospheric or under diminished pressure, and then to freeze out the remaining gas by the use of liquid air, just as in the experiments with liquid hydrogen.

The first vacuum tube was an electrodeless one, the air had not been dried, nor the glass specially cleaned. On spectroscopic examination it showed hydrogen lines bright along with the second or compound line spectrum of the same gas, and a series of bright bands defined on the less refrangible side; diffuse on the more refrangible, which occur in the yellow, green, blue, and indigo. These bands were found to be identical with the carbonic oxide spectrum. With a Leyden jar in the secondary circuit the line spectrum of hydrogen disappeared, leaving the second spectrum fainter; but the carbonic oxide bands remained bright, and there was no appearance of the hydrocarbon spectrum. The second tube had aluminum electrodes, and, like the last, had no special treatment in filling in the air. This tube showed also the line spectrum and the second spectrum of hydrogen; the latter being bright along with the carbonic oxide spectrum; but on sparking the latter disappeared. No appearance of the hydrocarbon spectrum could be detected, but there was a suspicion of bands in the indigo like the negative pole spectrum of nitrogen. The addition of a Leyden jar brought out nothing new, only intensifying the line spectrum of hydrogen, while leaving the second spectrum bright. In neither of the above tubes could any lines of nitrogen or oxygen be recognised. The third tube was filled with air drawn over cotton wool, red-hot copper oxide, and phosphoric pentoxide, no rubber joints being employed. The spectrum showed the carbonic oxide bands and the hydrogen line spectrum as before. Only the second hydrogen spectrum was feeble. There was a yellow line W. L. 5849, identical with one occurring in the natural gas from the King's Well at Bath. In a paper on "The Liquefaction of Air and the Detection of Impurities,"* the separation of helium from this gas is described by liquefaction and fractionation, and it was observed that during the sparking the helium lines were well marked along with "*others, the origin of which must be settled later.*" It was further observed, "*With a modified form of apparatus it will be possible to collect any residuary gas from the use not of 3 cubic feet of air or Bath gas, but from hundreds of cubic feet of such products.*" The helium and other associated material was shown to be more volatile than nitrogen. Pursuing this course of investigation in the summer of this year, the volatile portion of air was examined, when the presence of material giving the same lines as Bath helium was recognized. While this investigation was in progress, Professor Ramsay and Dr. Travers observed the same spectrum in the more volatile portion of argon which they have associated with a new element called neon. The use of liquid hydrogen, as described, proves that the most characteristic line of neon in the yellow, about W.L. 5849, can be detected in 25 c.c. of ordinary air, and the presence of helium in the atmosphere is confirmed.†

---

* 'Chem. Soc. Proc.,' November, 1897.

A fourth tube, filled like the preceding one, had a phosphoric pent-oxide tube left on. This showed again the carbonic oxide bands, but no hydrogen lines could be detected; while the oxide of copper ought to have removed all free hydrogen and transformed all the organic matter into carbonic acid and water. Yet it appears that the spectrum of the carbon compounds is difficult to remove from electrodeless tubes, probably owing to carbonic acid coming from the glass. There were some broad diffuse bands that may arise from the drying agent. The absence of hydrogen in this tube suggests that its presence in the third tube was due to vapour of water coming slowly from the glass. I am greatly indebted to Professor Liveing for making a careful examination of the spectra of these tubes.

---

† In a paper along with Professor Liveing, "On the Spectra of the Electric Discharge in Liquid Oxygen, Air, and Nitrogen," 'Phil. Mag.,' 1894, we noted that during the distillation and concentration *in vacuo* of liquid oxygen and air under diminished pressure that two bright lines appeared in the spectrum at wave-lengths 557 and 555, and that one of these lines was very near the position of the auroral line. These lines are now attributed by the same chemists to a new element, crypton.

Sir William Crookes was good enough to prepare two tubes with platinum electrodes, which he sparked in vacua till all hydrogen disappeared, and then filled with dry air, but without the use of red-hot copper oxide or any agent for the absorption of carbonic acid or the destruction of organic matter. After the cooling with liquid hydrogen, he found on spectroscopic examination, in one no hydrogen, but two faint lines, one about 5852 W.L. and the other 5676 W.L. The second tube showed the same yellow about 5852, the helium line along with 5939 and 6145, the hydrogen lines C and F, and some red lines. The observations of Crookes confirm the presence of neon, helium, and hydrogen. The absence in his tubes of the carbonic oxide spectrum is important, seeing all the electrodeless tubes gave this spectrum. In these tubes the vacuum was very high, and it was difficult to observe the gaseous spectrum. Still, the fact of finding hydrogen in one and not in the other, leaves the presence of free hydrogen in the atmosphere as a question for further inquiry. The tube that did not contain hydrogen was heated very hot in order to get a discharge, and then the spectrum showed some bands like the negative glow of nitrogen. Occasionally, a jar discharge was got to pass, and when this took place the nitrogen lines could be seen. An electrodeless tube filled carefully with oxygen made from fused chlorate of potash, which was contained in an extension of the vacuum tube gave nothing but the carbonic oxide bands. In future experiments it will be easy to concentrate all the most volatile material in air or other gases, and thereby to make a more thorough examination of the spectrum. In the meantime my object is to show one of the scientific uses of liquid hydrogen.

I have to thank Mr. Robert Lennox for efficient aid in the conduct of the difficult experiments. Mr. Heath has also helped in the work.

PRODUCTION OF CATHODE RAYS BY ULTRA-VIOLET LIGHT

By P. Lenard

(From the Sitzungsber. der Kais. d. Wissensch. in Wien' vom 19 October 1899[1])

[359]

The property possessed by ultra-violet light, discovered by Hertz and first demonstrated in a simple manner by Hallwachs, of expelling negative electricity from bodies has been investigated in many of its characteristics. One has been able to penetrate into its mechanism in so far as to determine the paths of the escaping electricity in air-filled and also in rarified space.[2] What, however, the carriers of electricity along these paths may be, has remained in doubt.

1. Researches on the "Disintegration of Bodies by Ultra-Violet Light"[3] have shown that possibly ponderable material parts of the body subjected to radiation may be those carriers. That such an immediate inference from the results of previous experiments is hardly justified special researches have shown me, of which one will be here touched on.

A clean surface of sodium amalgam in an atmosphere of hydrogen was subjected to radiation for such a length of time that 2.9×10^{-6} coulombs of negative electricity escaped from it, and the electric field was so impressed on the amalgam that the aggregate quantity of electricity must have been carried to a clean platinum wire. If sodium atoms had been the carriers, their [360] aggregate mass would have amounted to 0.7×10^{-6} mg. corresponding to the electro-chemical equivalent of sodium; and still more if larger parts of sodium had been the carriers. Now according to Bunsen, less than 0.3×10^{-6} mg. of sodium is detectable in flame with the greatest clearness. When, however, the platinum wire, which received the carriers, was tested in the flame there was no trace of sodium reaction.

2. To the other inference, which is indicated in the title of this work, I was led by the marked unipolar character of the photo-electric effect, as has been established beyond doubt especially by Elster and Geitel[4)], together with the knowledge that cathode rays may be important carriers of negative electricity[5)]. I was strengthened in this inference, after experiments with negative results, by a remark of Right.

He finds [6)] that the discharging action of light on a body with a large negative charge increases as the air is more and more rarified up to maximum which occurs at that pressure "at which the air most easily assumes an electric charge," but that it decreases with further rarification. He finds further that the action of light on an originally uncharged body in bringing it to a positive charge by the expulsion of negative electricity always increases with increasing rarification of the air and he adds the remark that both properties of the photo-electric action clearly cannot be the results of a single cause.

The present research begins at this point. When many phenomena are superposed on one another, one must endeavor to isolate a particular one. I endeavored, therefore, to study the phenomena when the air was excluded, whereby it was above all to be decided whether with the passage to the most extreme vacuum a reversal did not occur with cessation of the action, as is really the case with other discharge phenomena.

3. The apparatus employed, an evacuated glass [361] tube with sealed-in electrodes, is represented in Fig. 1 to one third scale size. U is the electrode to be subjected to radiation, a disc of clean aluminum foil of 1.5 cm. radius. Of the same size and material is the

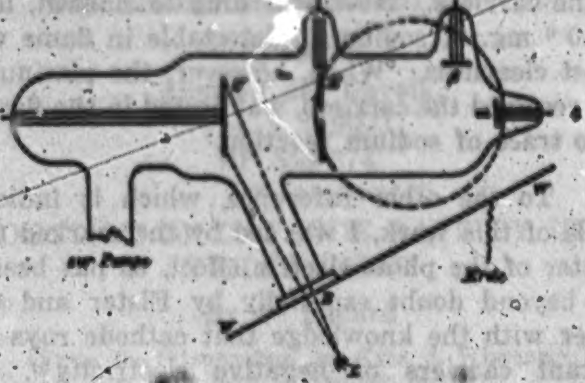

Fig. 1.

second electrode E which is placed parallel to the first and which is always grounded. The 5 mm. side opening in the electrode E as well as the additional electrodes α and β were not present in the first experiment (3, 4). The light source was as usual formed by the 15 mm. spark path of a large inductorium provided with a Leyden jar; the sparks jump between zinc wires which yields much ultra-violet light. A shield B composed of tin foil of 4 mm. breadth prevented the light from striking any parts of the tube interior other than the electrode U. The shield was laterally extended in the form of a sheet, indicated by WW in the figure, which protected the tube and the measuring instruments from the electrical action of the light source. The tube was closed at B by a 3 mm. thick quartz plate. The light source was always more than 4 cm. distant from B.

By prolonged heating and the discharge of a large inductorium we bring the tube into the steady condition in which it no longer passes the discharge through, the discharge passing outside around the tube. The mercury air pump[7] produced then no detectable gas from the tube in time intervals of hours.

If we now connect U with an electroscope its [362] leaves collapse instantaneously when negatively charged, when U is illuminated, and also their separation is rapidly reduced when a Leyden jar of medium size is connected to them. Positive charges remain or decrease with extreme slowness[8]. With the quadrant electrometer it is shown that the originally uncharged electrode under the influence of the light assumes a positive charge which increases up to a limit of about 2.1 volts. All these phenomena are completely suppressed when a thin sheet of mica is placed between the light source and the apparatus. In short, all the characteristic actions of ultra-violet light, known to exist in air, occur also in the most complete vacuum and indeed with striking intensity. Quantitatively we shall establish soon (4) a sharp distinction between the action occurring here and that occurring in rarified air. It may also be remarked here that the cooling with solid carbon dioxide and ether of a vessel containing phosphorous-pent-oxide located between tube and pump did not affect the quantities of escaping electricity to be measured.

In regard to the photo-electric action, the experiment seems to me to teach that this to a first order has nothing to do with the air. A further point of interest of the research resides in the fact that it shows electricity to exist in the most extreme vacuum which, according to prior knowledge, one must have pronounced impossible. The same thing has been observed previously, and for the first time, with cathode rays which were produced by gas discharge[9], and it is noteworthy that it is only negative electricity which appears in the extreme vacuum. In order to take into account these relations I shall in the following designate with the particular name quanta the discrete quantities of electricity to be [363] observed here and which, as will be shown again, are endowed with inertia and which in motion constitute cathode rays, as previously known.

4. A measurement of the quantity of electricity driven into the vacuum by the action of the light is afforded if one allows this quantity before entering the electrode U to flow through a very large resistance in series with this electrode, and measures the potential difference between the ends of this resistance by aid of

an Exner electroscope or a quadrant galvanometer. This measuring instrument and the resistance composed of twine or graphite, were placed inside a conducting enclosure, insulated from ground to which the negative electricity was conducted at measurable voltage.[10] The difference of this last voltage and that observed between the ends of the resistance is the electrode potential of the following table; opposite are the quantities calculated from Ohm's Law.

TABLE I

Potential of the Electrode subjected to radiation.	Escaping Quantities of Electricity.

[364]

If we consider first the upper part of the table, we see that the quantity of electricity escaping per second is within wide limits independent of the voltage present. In the second part of the table, on the other hand, that is, for voltages under 100 volts, the quantity of electricity discharged decreases markedly with a further decrease of voltage. This relation does not admit of immediate explanation; for if the impressed voltage has a true effect on the radiation from the electrode, it would have to show itself most pronouncedly at the highest voltages; this is, however, not the case. The explanation which I have formed is that at insufficient impressed voltages the radiation is not indeed diminished, but that a part of the already emitted quanta are returned to the electrode under the action of their own forces. That this effect occurred in our research from 100 volts downward depends on the peculiarity of the applied light source of having extraordinary intensity for extraordinary short time intervals. This point will not be further entered on here; it suffices to have indicated for further application definite and steady quantities of escaping electricity in our research. There may be further noted the obviously explicable decrease to zero of the escaping quantity, shown in the third part of the table, when the impressed voltage is positive; when therefore the removal of the radiated quanta is opposed (cf. 8). The voltage +2.1 volts, to which corresponds the quantity zero, is the same as that attained by radiation by an originally uncharged electrode.

For comparison of the relations in vacua with those in air of different rarefactions we may here place the following results of a series of related experiments with our apparatus, undertaken for this purpose.
[365]

TABLE II

Potential of Electrode subjected to Radiation	Pressure in mm. of Mercury 0	0.002	0.03	0.7	20	209	760
Volts, negative	Quantity of Escaping Electricity Coulomb 10^{-10}/sec.						
800	20.2	21.6	47	3.4	0.62	0.12	0.05
4000	20.3	26.2	..	..	40	1.41	0.42
10000	20.2	28.2	..	..	...	...	0.93

Blanks in the table indicate that the air could no longer sustain the applied voltage.

One sees from the table that the Emission Constant is only to be determined at zero pressure. At 0.002 mm. air pressure and more markedly at high pressures the escaping quantity of electricity increases very markedly with increasing voltage, which indeed was the result of previous researches on this subject. In the conclusion (9) we shall return to the question of the air.

5. As regards the question of the path which the quanta escaping from U take, we can make our start again from Righi's basic work which shows that in ordinary air these paths are given by the lines of force of the electric field, but that with increasing rarefaction of the air they approximate more and more straight lines.[12] We inquire now as to whether in a vacuum also we can arrive at the formation of distinct separate rays. The opening in the electrode E (cf. Fig. 1) and the neighboring electrodes α and β are now made use of. If U is sufficiently charged, say to about —30000 volts corrseponding to a spark length of about 1 cm., one observes in an Exner electroscope connected to α a divergence of negative sign beginning with the illumination and increasing slowly. The electricity therefore passes through E to α. That the electricity does not occupy the entire cross-section of the tube is shown by the fact that on the side electrode β a divergence is not obtained; obviously the quanta form a beam which [366] coming to the opening in E, pass through to α.

We find this confirmed when we test the putative beam (ray) by its magnetic deflectability which is to be expected. For this purpose a wire coil is brought close to the tube either above or below; the common axis of the coil is vertical; its windings appear in Fig. 1 as a dotted circle. If now a current of suitable strength flows through the coil, it results that it would deflect to β a cathode beam identical with our beam, so that we obtain the divergence of the electroscope now on β while it is excluded from α, to appear again on α when the current is opened.

The behavior is therefore exactly that which is to be expected when cathode rays are emitted from U. Yet it is not possible to produce [13] cathode rays in our extremely evacuated tube by the usual application of electric force alone; rather ultra-violet light is the means to render possible this production also in a perfect vacuum, and indeed in accordance with the information contained in Table I, not only with large but with as small impressed voltages as one desires. As the immediate source of the quanta of our rays the illuminated electrode is indicated while in the usual discharge tube it appears to be the indispensable gas.

6. For the quantitative study of the magnetic deflectability of our rays, we use instead of the electroscope a quadrant electrometer which may be connected with α or β. The conductor connected to the instrument in the screening metallic enclosure is connected to ground by a shunt conductor in series with a large graphite resistance. By this means the occurrence of disturbing potential differences in the space between E, α and β is avoided, and at the same time the measurement of the quantities or electricity caught by α or β is made possible without time observations by reason of the constant deflection of the electrometer. The outer walls of the tube for the following experiment are cov- [367] ered with tin foil from E to α and β and out of this only the insulated lead wires of the last two electrodes project; the enclosure as well as the particular electrode which is not used in the experiment, are connected to ground. To the illuminated electrode two large Leyden jars are connected to hold its potential constant. After this potential is brought to the desired value the experiment is so conducted that the electrometer deflections, corresponding to a series of different currents in the coil are measured for both α and β[14)].

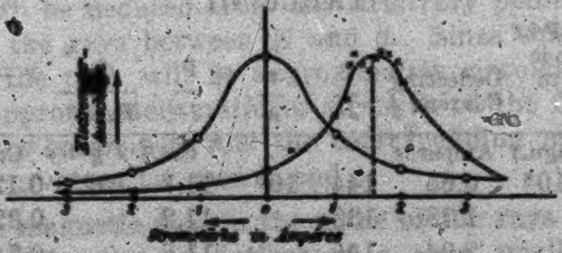

Fig. 2.

Fig. 2 shows graphically the results of such an experiment and at the same time gives a picture of the boundary of the rays. The curve which is symmetrical with respect to zero current and whose points are indicated by circles refers to the electrode for both α, and β. To determine the location of the axis of symmetry of the last curve (denoted by a dotted line) and also the current which deflected the axis of the ray to the center of the electrode β was the object of every experiment. The second and third current values J, given in Table III are mean values of such graphical determinations. The first current value, corresponding to the smallest potential of U, could only be gotten by rapid variations of [368] the current with simultaneous electrometer readings; for, on account of the weakness of the rays at this low voltage, the spark illumination had to be replaced by an intense zinc arclight[15)] which latter was of very fluctuating intensity. The potentials of the electrode U, indicated in the first column of the table, were determined during the experiment by the divergence of a suitable electroscope. The calibration of the electroscope gave the highest or the mean applied potential corresponding to a sparking distance of 3.40 or 0.880 mm. measured between clean spheres of 1.0 and 0.7 cm. radius respectively, from which the corresponding values P of the table follow. The electroscope used for the lowest potentials was tested electrostatically on spark lengths with the aid of large capacities downward and upward by voltages measurable by current flow; from the calibration curve so obtained the first number P is taken.

TABLE III

Potential P of the electrode subjected to radiation.	Deflecting Current J	$\frac{P}{J^2}$	$\frac{\varepsilon}{\mu} = \frac{P}{J^2} \cdot \frac{Z}{H_1^2R^2}$	$v = \frac{2P}{H_1RJ}$
C.G.S. (magn.)	Amperes		Cm.$^{1/2}$ g$^{-1/2}$	Cm. sec.$^{-1}$
607 . 10^8	0.65	144 . 10^9	11.7 . 10^6	0.12 . 10^{10}
4380	1.78	138	11.2	0.32
12600	2.94	146	11.8	0.54

With the data so obtained, we now test quantitatively the assumption that the particles of our rays set in motion by the light with the initial velocity v_0 behave like the particles of a cathode ray, that they therefore in the first place are accelerated, in a uniform electric field under the potential difference P, to the velocity v in accordance with the equation, $v^2 - v_0{}^2 = \frac{\varepsilon}{\mu} P^2$ 16), [369] and that, secondly, in a uniform magnetic field H at right angles to their motion have the radius of curvature

$$R = \frac{v}{H} \cdot \frac{\mu}{\varepsilon}$$

Since we estimate H from the current J we write $H = H_1 J$ where H_1 denotes the field due to a current of one ampere.

We add the special hypothesis of a very small initial velocity and therefore set $v_0 = 0$. It follows then $\frac{P}{J^2} = \frac{1}{2} H_1{}^2 R^2 \frac{\varepsilon}{\mu} =$ constant, a relation which is confirmed by the third column of Table III. The whole of our assumptions meet with no contradictions. Concerning the real magnitude of the initial velocity, we shall later obtain information (8).

7. In order to calculate the density relation $\frac{\varepsilon}{\mu}$ and the velocity v, a knowledge of H_1 and R besides $\frac{P}{2}$ is needed, two corresponding values of field and radius which can be deduced from any arbitrary point on the path of the rays between E and β. Since this entire part of the path will be approximately circular owing to the approximately uniform strength of the field, we choose the mean field and the corresponding mean radius of curvature between E and β.

The magnetic field in the plane of the rays was investigated by the oscillations of a very small highly magnetized needle loaded with lead. The following are the observed oscillation periods.

Distance from the axis of the coil	0	1	2	3	4	5 cm.
Oscillation period with 1 amp. current	1.08	1.11	1.23	1.51	2.21	4.15 sec.

[370]

At 6 and 7 cm. separation from the axis, the position of equilibrium of the needle departed greatly from the direction of the axis of the coils which was placed normal to the meridian. The magnet field was therefore at this place already of the same order of magnitude as the field of the earth and therefore out of consideration for our purpose. The electrode E was separated 3 cm. and the electrode U 6.6 cm. from the axis of the coil. The magnetic field at the center was calculated as 16.0 C.G.S. units for a current of one ampere, from measurements of a very finely adjustable coil system. From this with the aid of the oscillation period, the mean magnetic field between E and β was calculated as $H_1 = 13.0$ C.G.S.

The mean radius of curvature is the radius of the circle which goes through the centers of E and β and whose direction is given at E. If this direction coincides exactly with the common axis of U and E, the radius, according to measurements made on the tube, would be 8.7 cm., but even before passing E the ray is influenced by the edge of the field of the coil and although this effect is small it nevertheless causes the ray to be deflected through a small angle from the axis toward β before it passes E and this would slightly increase the radius of curvature. According to our equations the angle is given by

$$\frac{\sqrt{\sigma}}{H_1 R} \int_0^\sigma \frac{Hds}{\sqrt{s}}$$

where σ is the distance of U from E on graphically evaluating the interval and making use of the above approximate value of the radius the angle becomes 5° 12′. The corrected radius is therefore 12.1 cm.

The values of $\frac{\epsilon}{\mu}$ which can now be calculated are given in the fourth column of Table III. They differ from the value of $4.6 \,.\, 10^6$ which I previously obtained with cathode rays[17]. There is no reason to compel us [871] to look upon this difference as genuine, since those experiments as well as these were not undertaken for the purpose of this determination and at that time they could not be undertaken for such a purpose[18]. It would therefore be the more interesting to make a direct comparison between the rays produced by ultra-violet light and those produced by gas discharge. For this purpose suitable quantities of air were let into the tube and the electrode U was connected with the influence machine. The phosphorescent patch which was sharply bounded covered almost the entire electrode α. The currents necessary to make the fluorescence cover the electrode β were $J = 1.7$ to 2.5 amperes for potential differences $P = 3300$ to $9300 \,.\, 10^8$ C.G.S., which gives $\frac{P}{J^2} = 114$ to $149 \,.\, 10^9$ and this is in good agreement with the values obtained with our rays (cf. Table III, column 3). This experiment is, of course, not decisive, because the objection may be raised that the rays in the last named experiments were not pure in that they were produced in the midst of a disturbing gas, and furthermore, it may be doubted whether the whole potential difference between the electrodes can be reckoned with here, since it is used not only for accelerating but also for the production of the rays. The question regarding the constancy of the density relation $\frac{\epsilon}{\mu}$ seems to me to be still open[19]. The velocity v of the rays given in the last column of Table III shows that here we partly deal with rays that are slower than any that have thus far been investigated. The velocity of the rays which was produced under the influence of a potential difference of 607 volts—corresponding to a mean divergence of an ordinary electroscope—is about $\frac{1}{30}$ of the velocity of light. It is not to be wondered why these rays did not produce phosphorescence on the glass wall of the tube. It is also explainable why in my experi- [372] ments very much faster rays that were produced with high voltages remained invisible, because cathode rays that I observed before and which carried quantities of electricity of the same order of magnitude could only be noticed on the glass in a completely dark room while in the present experiments a good deal of unavoidable diffused light was present. The use of suitable phosphorescence screens would be appropriate in this case.

8. A few more conclusions can be drawn from the observations. In the first place, we see that on account of the weakness of the rays that were produced at 607 volts (cf. 6) the radiation from the surface which was subjected to the ultraviolet light did not take place normally to the surface as would be the case in an ordinary discharge tube, but it was diffused in all directions, because we see from Table I that the same quantity of electricity is emitted with this voltage as with higher voltages which, however, gave much more intense rays back of the diaphragm E. This difference in intensity can be accounted for when the radiation takes place in all directions. In this case the higher the voltage the more the rays are bent under the influence of the electric field between U and E so as to have a common normal direction and so more rays would pass through the opening in E. Also the necessity of avoiding an illumination of the edge of U when we want to obtain pure rays behind E under the influence of small voltages can be accounted for by the diffuse radiation, (compare notations page 367). For if not made innocuous by strong forces this would permit the radiation to pass over the outer edge of E.

The diffuse radiation is also closely connected to a finite initial velocity of emission. In order to obtain an estimate of the value of the initial velocity in our experiments I conductively connected E and U together and to earth so that there was no electric force between them, at least not at the beginning. At the same time two coils were so mounted that the region between U and E was in the center of their field. These coils were so mounted that the magnetic field of the earth could [373] be compensated with the help of suitably chosen currents. This was done in order, first, to see if the earth's field would have any influence on the radiation20). This was found not to be the case. There was no noticeable difference between the quantity of electricity emitted with or without the earth's field. If, however, the magnetic field between U and E was increased more and more, until at a field of about 6 C.G.S. there was a distinct diminution in the quantity of electricity emitted, with a field of 16 C.G.S. almost the whole radiation was suppressed21). This behavior can be explained as follows:

The quanta which in the absence of the external electric field have a constant velocity in all directions from the center of emission (cf. note 14) travel in circles or spirals in the homogeneous magnetic field. The radius of these paths becomes smaller with increase in the strength of the magnetic field. If the magnetic field is sufficiently large, one of these paths will not strike any body in the neighborhood any more, but will be bent back to the surface of the emitting electrode, and this is the beginning of the influence of the magnetic field on the escaping quanta 22). The diameter of the path that is bent back first is, with our apparatus, of the order of the distance between U and E, that is, 3.6 cm., and this corresponds to a field of 6 C.G.S., so that the velocity v_0 of emission is roughly 10^8 cm. per second.

The same result can be obtained by noting that the emission is reduced to zero when the potential of U becomes 2.1 volts positive (Table I). This process can be looked upon in this way, that the potential P is just sufficient to return all the quanta that have been emitted in all directions with the velocity v_0 to the electrode before they can strike any body in the neighborhood. The [374] velocity can then be calculated from the equation $v_0 = \sqrt{2 P \frac{\varepsilon}{\mu}}$ since the glass wall can be looked upon as sufficiently conducting to have the same potential as E—that is, ground potential. This also gives for v_0 10^8 cm. per second.

An initial velocity of this order of magnitude could be overlooked in our deflection experiments (6), since it is only $\frac{1}{10}$ of the least velocity dealt with. They would therefore be completely covered by an error of $\frac{1}{100}$ in the experimental observations.

9. Thus far we have only considered the phenomena in vacuum. From the results here obtained, however, conclusions can be drawn for the case in which gas is present. These may be pointed out here. They seem to agree well with results that are already known. The cathode rays proceeding from the illuminated surface would be absorbed by the gas and would give up their charges to it. From then on the electricity is transported by the gas along those paths and with those relatively low velocities which Mr. Righi has found and also explained on the assumption of charged gas molecules. If the pressure of the gas is not very small the transportation of electricity will be in the form of cathode rays only in a very small section in the neighborhood of the illuminated plate, since the low initial velocities (8) of the emitted rays would mean great absorption[22]. For small gas pressures this layer would become thicker in proportion to the small absorption by the gas [23], and can therefore be more easily observed[24]. The diffuse radiation on the illuminated electrode [25] which was observed by Mr. Righi for low gas pressures and which he explained as due to the motion of the gas

molecules, might consequently be identical with the diffuse emission of the cathode rays found here.

[375]

The presence of the gas would cause complications, in view of the conductivity imparted to the gas by the cathode rays when the latter are absorbed[26]. The illuminated electrode is then surrounded by a negative charge and by a conducting atmosphere. This can be understood if we consider that in the presence of gas the quantity of electricity discharged in unit time increases with the voltage, and secondly that in gas much larger quantities of electricity can be discharged than in a vacuum (4, Table II). The fact that the discharge decreases again for high gas pressures contradicts this explanation. Difficulties are met in considering the case in which the substance was initially charged positively in air. For the explanation of this there is a want of knowledge of the properties of gases which have been charged and made conducting by cathode rays.

Defendant's Exhibit No. 10

NOTES.

1. With regard to the notes to paragraphs 8 and 9 of this paper, attention is called in this edition to the allied investigation of Mr. J. J. Thomson which has now been fully published (Phil. Mag. 5, 48, page 547, 1899).

2. A. Righi, Mem. della Reale Acad. di Bologna (4), 9, p. 369, 1888, and Atti. della Reale Acad. dei Lincei (2) 6, p. 81, 1890.

3. P. Lenard and N. Wolf, Wied. Ann. 37, p. 443, 1889.

4. J. Elster and H. Geitel, Wied. Ann. 57, p. 24, 1896.

5. Cf. Wied. Ann. 64, p. 279, 1898.

6. A. Righi, Atti della Reale Acad. dei Lincei l.c.

7. The raps pump was used.

8. This was shown to be strictly dependent on the illumination within the tube; if besides the surface of U other parts of the tube were illuminated the decrease of the positive charge could be accelerated. Since [illegible] under normal conditions scattered reflected light strikes, for example, the electrode E, the above mentioned small loss of positive electricity appears to be explicable in the meaning of Elster and Geitel (l.c.).

9. Cf. Wied. Ann. 64, p. 279, 1898.

10. Concerning the mode of voltage measurement, cf. p. 368. The resistances were determined by the time of discharge of measured capacities.

11. Except at this voltage in my research no escape of electricity was detected in the absence of light.

12. A. Righi, Atti (l.c.).

13. At least not by forces which the glass of the tube employed was capable of continuously withstanding; cf. remarks with Table I.

14. It is to be remarked that in this experiment a quartz lens placed between L and B focused the ultra-violet light on the center of the electrode U, there illuminating a faintly bounded ellipse of about 10 mm. mean diameter (cf. 8).

15. A. Righi, memo. della Reale Acad. di Bologna (4), 9, p. 379, 1888.

16. A special test of this deduction I ~~carried~~ through with cathode rays previously (Wied. Ann. 65, p. 504, 1898). Subsequent to this work opportunity was given me to remark on the observations of de Condres (Verh. d. Phys. Ges. zu Berlin 17, p. 17, 1898) already published but unknown to

me, in which an influencing of the rays by electric force parallel to the rays had been shown, and moreover in the sense of the above equation. Almost simultaneously Wiechert's experimental determination of the propagation velocity of cathode rays had placed the subject on a new basis (Gött Nachr. Math. Phys. Klasse, 1898, p. 260).

17. P. Lenard, Wied. Ann. 64, p. 287, 1898; 65, p. 508, 1898.

18. As long as still inexplicable related phenomena come into play, an exact measurement is not in general possible. As a related phenomenon of this kind in the present experiment, I might name the double maximum of the deflection curve of Fig. 2 which was visible in every case and which was often very pronounced. As far as possible errors and known origin are concerned, I would give preference to these experiments over the previous ones.

19. Cf. also A. Shuster, Wied. Ann. 65, p. 877, 1898.

20. The induction apparatus producing the illuminating spark was placed 6 m. distant from the tube in the recorded experiment.

21. This is the phenomenon simultaneously discovered by Elster and Geitel (Wied. Ann. 41, p. 166, 1890) and Righi Atti, (l.c.).

22. As far as I can tell from an abstract at hand, the same conception of the disfractive magnetic effect has just been published by J. J. Thomson (Phys. Zeitschr. 1. October 1899).

23. Cf. Wied. Ann. 56, p. 255, 1895.

24. Indeed, in the cited notice (abstract) J. J. Thomson announces observations which concern the photo-electric discharge in a shell of rarefied gas and permit this to act as cathode rays.

25. A. Righi, Atti. l. c.

26. Cf. Wied. Ann. 51, p. 240, 1894.

TRANSLATOR'S NOTES.

(To Lenard's paper on
"Photoelectric Action")

The German word here translated as "electron" is "Quant." This is a word peculiar to Lenard, which he used for years to designate what all other German's were calling "Elektron". In his latest available article in volume 48 of the Annalen der Physik he uses both words to designate the same thing. (p. 496) That he is speaking of electrons in the article here translated is obvious from the fact that he gives 10^7 for the ratio of the charge of the "Quant" to its mass. This differs by some forty per cent from the value now accepted for the electron, but is of a totally different order of magnitude from the value for any other possible kind of charged particle.

The word translated as "ion" is "Träger."

The terms "carbon", "black", and "lampblack" have been used at different places to signify the coating of carbon deposited by a smoking flame on a metal surface. In this case it was obtained by burning turpentine. A "blackened" surface is one so covered. The corresponding German words are "Russ" and "berusst."

[TRANSLATION]

PHOTOELECTRIC ACTION

(Ueber die lichtelektrische Wirkung)

by

P. Lenard

Annalen der Physik, Vol. 8, p. 149, 1902

[149]

In an earlier communication, I have shown that ultra-violet light falling on a body may excite cathode radiation from it[1]. This production of cathode rays was found to be independent of the presence of a gas; contrary to all previously known methods of production in discharged tubes, it took place even in the highest vacuum[2]. A characteristic was that as in a vacuum electric forces had no influence on this excitation. The quantity of radiation was not at all affected by increasing the force at the negatively charged illuminated surface from 100 Volt/3.6 cm. to 45,000 Volt/3.6 cm. This was in accordance with the hypothesis that the light produces the rays not outside but in the interior of the body where it is absorbed; and in such a manner that negative electrons are set free with given initial velocities, so that they can make their way out of the substance. In this case the outside electric forces would operate simply to produce an acceleration or a retardation according to its direction, of the emitted electrons. A retarding outside force corresponding to a positive charging of the illuminated body can cause electrons already emitted to return to the body and thus apparently stop the emission; this was also observed. It was surprising, [150] however, that a diminution of the amount emitted—according to our conception, a return of electrons already emitted—took place when the outside force was accelerating and less than 30 Volt/cm. while much greater forces have no further effect on it. Here we had to assume the presence of a particular retarding force of still unknown origin. In the interim, I have been trying to obtain further knowledge about this and about the general process of producing the rays[3].

10. I succeeded in making the rays visible on phosphorescent screens which made observation much easier. However, I shall here report only on the results of experiments with electrometers only, in which, first, the forces of electrical nature acting at the surfaces of conductors have an opportunity to make themselves manifest in a new way and, second, the initial velocities of the rays can be thoroughly measured. In respect to those forces we found, for example, that there is not a single clear indication of the existence of a specific attraction between conductors and electricity as was assumed to explain the contact potential differences of metals (38). In respect to the initial velocities, we find they are not of uniform magnitude and that for every conductor and every kind of exciting light there is a special distribution of velocities (22, 23, 26, 36). However, the magnitudes of the initial velocities are independent of the intensity of the light (25) and this last result makes it seem probable that in the process of excitation the light merely sets the electrons free with velocities which they must already fully possess inside the atoms of the substance (28).

11. If the illuminated substance is in a space filled with gas the phenomenon becomes similar to the action of light discovered by Hertz and Hallwachs (9, 47). There was a single apparent objection to this idea, to wit, the rigorously uni-polar character of this action, [*i.e.* of Hertz & Hallwachs]. For if the illuminated body [151] sends out cathode rays with the initial velocities peculiar to it and to the exciting light independently of the outside force—and hence, also, when it is positively charged—these cathode rays will traverse some of the gas even if they are quickly pulled back by the outside force and will consequently (according to previous knowledge)[4] make it electrically conducting. But if the body has a conducting layer of gas next to it, it will

lose its charge; and this is contrary to experience. It will be shown here that gases are made conductive by cathode rays only when the rays have a velocity exceeding a certain minimum (39, 40, 42, 43); and since we furthermore find that the highest initial velocities possessed by any detectable number of the rays excited by light, lie under this minimum, the contradiction disappears (46). The velocity of the rays studied in the present work is of the order of 10^7 to 10^8 cm. per second of about one one-thousandth of the velocity of light, consequently much smaller than before (7). It is seen that these slow rays must possess to a very high degree the properties of spreading out diffusely and of being absorbed in gases for after passing through only a few gas molecules (41), while the rays which I first studied having about one-third the velocity of light could pass through 5000 gas molecules before their path became noticeably curved or their motion slowed down.

EXPERIMENTS IN A VACUUM.

12. The present experimental runs were not carried out in the most extreme vacuum. I evacuated always to the limit of the mercury pump but did not apply any special means to remove the remaining gas from the electrodes and the glass walls, and used cement and greased joints. Since the principal features of the phenomenon in extreme vacuum had already been investigated (3 to 8), this seemed permissible⁵⁾.
[152]

13. The apparatus is shown in Figure 1. U is the electrode to be illuminated, which is a circular aluminium disc of 3.4 cm. diameter completely covered with turpentine black. Opposite it stands the metal disc E of the same size and similarly covered with black; part of it is cut away (e Figure 1 a) so that the narrow beam of light which traverses the diaphragms BB and gg from the source L, can reach U without touching E. This was completely avoided by setting the source of

light carefully. The plate E can be moved perpendicular to its own plane so that the distance UE can be altered. For distances UE less than 10 mm., a special electrode E_1, Figure 1 b, is put in place of E. This one has a conical metal tube r to give a free path to the beam of light; one mouth of this tube lies in the same straight line with the diaphragm gg and the other opposite U when the distance UE is equal to 5 mm. This plate E_1 is likewise covered with black together with its tube.

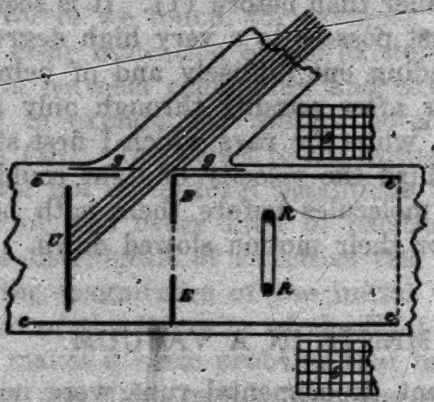

Fig. 4.

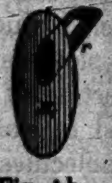

Fig. 1b.

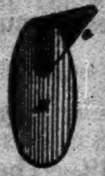

Fig. 1a.

At the beginning of every run a measurable potential difference is established between U and E [153] by using storage batteries; directly for high potential differences and with a potentiometer arrangement for lower ones. The plate U or E, for which we were to determine the change in charge due to illumination, was connected with a quadrant electrometer. The box containing the electrometer which extended over all the connections and over the pair of plates U and E (WW in Figure 1 and the diaphragm BB being parts of it), was brought at the beginning to the same potential as the plate connected with the electrometer. At the beginning of the observation we broke a spring contact which had been connecting the plate with the box; the charge on the plate then changes because of the action of the light and the electrometer gives the change. Since the potential difference between the two plates alters at the same rate, it is necessary to work only with small deflections of the electrometer. Unless we were using high potentials, the change of which is without influence (4), we added such a capacity to the electrometer and so adjusted the duration of the illumination[6] that the deflections amounted to only a few scale divisions corresponding (for average sensitivity of the electrometer) to a few hundredths of a volt[7]. The smallness of these deflections did not limit the attainable accuracy for the readings of the electrometer are reliable to .02 scale divisions[8] and the known adequate sources of ultra-violet light vary so much in their intensity that a great number of observations have to be taken on this account alone.

[154]

14. The quantity emitted in unit time is proportional to the intensity of the light. The total quantity emitted under the influence of the light is observed, according to our hypothesis (4), when there is a sufficiently great outside accelerating force. Two hundred volts were used for a distance UE of 40 mm. The light came from 6 mm. sparks (3) between zinc spheres. Known variations of the intensity of the light were produced by varying the distance between the sparks and the mica diaphragm gg; this diaphragm being smaller than BB always determined the cross section of the beam reaching U. The electrometer was connected to U. The results follow[9].

Column 5 shows that the light intensities varied in the ratio of 90 : 1.4, while the ratio between the effect Q and the intensity (Column 6) is as constant as was the source of light during their periods of time which [155] had to elapse before it could be readjusted. Not all the loss of electricity Q here observed took place by emission but only the largest part of it; a small part is due to the conductivity of the system (12, 45). The inverse relation is found in experiments in rarefied gases where the loss of electricity through conduction may

exceed that by emission (compare 4, Table II, .03 mm. pressure). Now, since experiments of this latter kind have likewise found the effect proportional to the intensity[10)] of the light, our experiments show that this proportionality holds also for pure emission.

15. The period during which a zinc spark spectrum line was being emitted was about 5×10^{-6} seconds in the experiments of Schuster and Hemsalech[11)]. In the present experiments it must have been yet smaller for the capacity used in the spark apparatus was less. Since the sparks follow one another at intervals of .0062 seconds, the intensity of this source of light, while it was actually shining, was more than 1300 times greater than its average intensity. These experiments, therefore, were really performed with extraordinarily great intensities even when the source of light was furthest away. However, I have found with a carbon arc light, burning as feebly as possible, at distances of from 34 to 268 cm. from the mica diaphragm, that the effect is still proportional to the inverse square of the distance

at least insofar as could be expected, considering the inconstancy of the ultra-violet intensity of such an arc; at least, there was not the slightest indication of any value of the intensity near which the effect might diminish rapidly to zero. If such a value exists it must be very low as we see especially from the effect of the light reflected from the blackened surface U, to be quantitatively discussed in (22). These very small quantities [156] of light falling on E produced a correspondingly small effect which was seen to be a sensibly constant fraction of the effect of the light falling directly on Y independent of its intensity; which can only be the case if the very small quantities of light reflected from the lamp black still have an effect proportional to their intensity. The intensities there observed were as much as 3 x 10^6 times smaller than the largest momentary intensities used in Table 4.

16. The following run (Table V) is given to show the trend of the radiation at various outside potential differences. It is graphically represented by the two

straight lines of Plate 1, Figure 1, marked with UE = 10 mm. The abscissa is potential difference. The ordinate is the quantity of electricity and points which belong together are connected with a straight line. The full line gives the quantity of electricity leaving U, the broken line the quantity arriving at E. These quantities we designate for shortness simply by U and E[12].

[157]

17. To this table and the corresponding graphs we append the following ideas, from which all that follows will proceed and which are justified thereby. For the sake of convenience in conceiving it, we divide the phenomenon into five separate stages which correspond to different ranges of magnitude of the outside force (compare Plate 1, Figure 1).

In stage 1 (large retarding forces) the entire quantity of electricity which the light causes to be emitted—we designate this quantity always by 1.00—is driven back to U before striking any object in the vicinity. In this stage the electrometer would show nothing if there were not some light reflected from U to E which produces an effect there. This effect is revealed by the small quantities of electricity which depart from E and arrive at U and which appear in Plate 1, Figure 1, as very small negative ordinates.

In stage 2 (retarding outside force, not so great) U begins to lose its charge steadily but nothing arrives at E; the part of the radiation which does not return to U goes to the glass walls of the apparatus (this is the part corresponding to the ordinate U). This is due to the tangential components of the initial velocities (8). The parabolic paths of the electrons beginning at the illuminated center of U do not quite reach E but do go so far over the edge of U that they finally reach the glass wall instead of returning.

In stage 3 (retarding force still smaller than in [158] stage 2) some paths extend as far as E and stop there so that the curve E begins to show positive ordinates. Of the total emission 1.00 a part, E, goes to E, another part, U-E, goes off sidewise to the glass walls and the third part 1-U goes back to U. The number of electrons going to E increases when the retarding force diminishes, as is shown by the rise of curve E. Since only such electrons can come to E as have velocities of which the normal component exceeds a certain amount corresponding to the potential difference UE, the shape of the curves in this stage will be suitable for finding the distribution of the initial velocities; of course, the sidewise escape of the electrons must be allowed for (18, 20, 22, 23).

In stage 4 the two curves coincide; the outside force which is now an accelerating force, brings all the electrons to E except those that return to U.

In stage 5, the accelerating force is so great that no electrons return to U and consequently the total emission—1.00 in our units—is measured. A further increase of the force produces no further alteration, as was completely proved up to very high values of the force in the earlier experiments (4, Plate 1).

18. Prevention of the sidewise escape of electrons by means of magnetic force.—A coil (SS in Figure 1) is slipped over the tube producing a magnetic field normal to U and E. This converts the tangential components of the electron paths into circles leaving the normal components unchanged. The sidewise escape of the electrons to the glass walls is, therefore, suppressed; however, the electrons which would have escaped except for the magnetic force do not go on to E but return instead to U as it should be (17, stage 2). This is shown as follows that the quantities reaching E—given in Columns 4 and 7 of Table VI—are not distinctly changed by the magnetic force while the quantities departing from U change (compare Columns 2 and 3 or 5 and 6 of Table VI), in such manner that they become nearly equal to the previously mentioned quantities E. The magnetic force, therefore, brings curve U nearly into

[159] coincidence with curve E which last remains unchanged; stage 2, therefore, vanishes.

The tests were carried out with the carbon arc light as well as with the spark[13].

19. A direct observation of the quantity of electricity escaping sidewise was made possible by introducing a metallic sheath (HH, Figure 1), covered with lamp black, against the glass wall between U and E[14]. When the magnetic field was raised to about 15 C.G.S. units (measured at the surface of U), the sheath no longer took up any negative charge. No electric force was applied; the distance UE was 40 mm., the radius of the sheath 2.2 cm., the radius of the spot of light on U 0.3 cm. From this we obtain for the largest value of the tangential component of the initial velocity, possessed by any detectable number of electrons, the value

$$\frac{15(2.2-0.3)}{2}\,\frac{\varepsilon}{\mu} = 1.4 \text{ x } 10\,\frac{8\text{cm}}{\text{sec.}}\,.\quad{}^{15)}$$

[160] It is, therefore, of the same order of magnitude as the largest value previously obtained approximately for aluminium (8) and later on more exactly for carbon (36) for the observed normal component.

20. Prevention of sidewise escape of the electrons by bringing the plates U and E close together. — Bringing the plates close together must have the same effect

as making them larger (17, stage 2). For given magnitude and given direction of the initial velocity, the maximum distance traveled in the normal direction is equal to half the maximum distance traveled sidewise. Consequently the sidewise emission must cease, when the distance UE between the plates is smaller than half the distance between the edge of the plate U and the edge of the spot of light; that is, smaller than 7 mm. Experiment confirms this also. We need only to determine the places where the effect on U or on E just ceases corresponding to the boundaries between stages 1 and 2 or between stages 2 and 3, (plate 1, Figure 1); these can be found very accurately. When these two points coincide the curves U and E coincide entirely, and the sidewise emission vanishes. Below are given the abscissae of these two points in volts.

TABLE VII.

Points of Zero Effect; Arc Light.

Distance UE	5	10	25		40 mm.
—x (U = 0)	1.10	2.4*	far over 1.2	1.20	far over 1,2
—x (E = 0)	1.06	1.0*	1.0	1.06 with mdgn. force	1.05

We see that for distances UE greater than or equal to 10 mm., —x(U = 0) is always much greater than —x (E = 0) so that there is a great deal of sidewise [161] emission; while for UE = 5 mm. these two quantities become nearly equal so that the sidewise escape is nearly prevented. For the distance UE = 25 mm. the table shows further that the zero point of U is displaced towards that of E by normal magnetic force while the latter point remains undisplaced (18).

21. The point where the effect is zero depends on the potential difference between the illuminatd body and its surroundings.—The constancy of the numbers x(E = 0) in Table VII shows first that the plate E

takes up no further charge when the potential difference between it and U has a value 1.0 to 1.06 volts independently of the distance UE. Now, since by what precedes (18, 19, 20) U always is equal to E when there is no sidewise emission, we have U = 0 when E = 0; whence follows the principle stated above. This principle is also required by the hypothesis from which we started (17).

In air the phenomenon is different is known[16]; in this case the action becomes zero where a certain density of a positive electricity or a certain value of retarding normal force has been attained on the illuminated surface. This behavior in air must depend on the behavior in vacuum and on the properties of air, to which we will come back (47).

22. **Initial Velocities; Reflected Light.**—When sidewise escape is excluded, as we shall always assume from now on, and the curves U and E coincide, their form yields information about the distribution of initial velocities (17 Stage 3). We must still take account of the effect of the light reflected from U to E. For this purpose we examined the vicinity of the point of zero action more carefully. The following tables give the

average values of 127 measurements in this vicinity carried out at the distance UE = 5 mm. which had previously been found sufficiently small; the sources were [162] the carbon arc and the zinc arc[17].

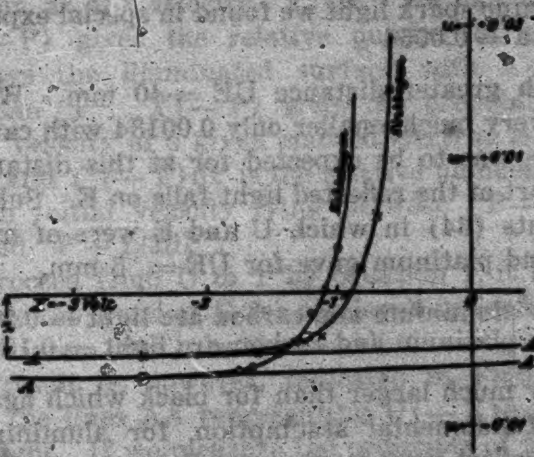

Fig. 2.

Figure 2 is a graphic representation of these tables on a large scale of ordinates. The curves approach a horizontal asymptote as was to be expected, for when the retarding force is sufficiently great there is no [163] emission from U to E, but all the emission from E produced by reflected light goes to U.

If the emitted quantities are proportional to the intensity of the light (14, 15), the quantity U(—a) simply signifies the fraction a of the light falling upon U which is reflected to E. But since the two plates U and E stand very close together and only the center of one of them is illuminated, it gives the fraction a of incident light which is reflected; that is, in the present case, the reflecting power of turpentine-oil-black. Correspondingly, the quantity U(—a) was found not to vary with the intensity of the light. The kind of light, however, had a marked influence. We take the following values from the last lines of Tables VIII and IX;

the trend of the curves is such that we may replace $U(-\alpha)$ by $U(-2.5)$

a, for turpentine-black and carbon arc light $= 0.00609$
a, for turpentine-black and zinc arc light $= 0.00463$ [10]

For zinc spark light we found in special experiments
$a = 0.0054$

at a much greater distance $UE = 40$ mm. We found $U(-\alpha)$ very much smaller only 0.00134 with carbon arc light; this was to be expected for at this distance only a small part of the reflected light falls on E. Subsequent experiments (34) in which U and E were of matt aluminium and platinum gave for $UE = 5$ mm.

a, for aluminium and carbon arc light $= 0.2069$
a, for platinum and carbon arc light $= 0.1066$

hence very much larger than for black which again confirm the fundamental assumption, for aluminium and platinum reflect very much more light than black.

Small a being thus known, we can start from the observed curve U which is a function of X, which we shall designate as $U(X)$ and obtain a curve $Y(X)$ free [164] from the influence of the reflected light. In the first place we have everywhere

$$U(X) = Y(X) + R(X)$$

wherein R represents the action of the reflected light alone; this must also be equal to

$$R(X) = Y(-X)\,a$$

From these, two equations follow:—

$$(1)\quad Y(X) = \frac{U(X) + U(-X)\,a}{1 - a^2}$$

In particular we have $Y(-\alpha) = 0$, $Y(+\alpha) = U(+\alpha) = 1$.

23. Outside Distribution of Velocities [20]—Since in what follows we shall have to do only with that component of velocity which is perpendicular to the surface of a body, we shall call this component simply the velocity: Then, if P represents the absolute magnitude of the retarding potential difference, $Y(-P)$ will signify the fraction of the total emitted quantity which

has a velocity greater than the greatest electron velocity which can be annulled by the potential difference P (17 Stage 3). This velocity—which conversely can just be produced by the potential difference P—we shall designate simply as the velocity "P"[21]. We can then say that $Y(-P)$ gives the relative number of electrons which leave the illuminated surface with a velocity greater than "P". $Y(-P)$ gives the probability that the initial velocity of a given emitted electron is greater than "P", and $Y'(-P)\,dP$ is the relative number of electrons with initial velocity lying between "P —1/2dP" [165] and "P + 1/2dP".

To proceed from U to Y by equation 1, it is necessary to note the trend of U for accelerating forces. This trend will later (29ff) be thoroughly investigated; the eventual result is, however, indicated in Figure 2 by means of the lines AA representing $U(-X)a$ for both kinds of light. If we measure the ordinates of the curve upwards from these lines we obtain Y; the factor $\frac{1}{1-a^2}$ may be set equal to unity without sensible error error in the case of carbon.

If we examine in this way the curve for carbon arc light, (for example) we deduce, first, that no definite maximum initial velocity can be assigned, but that velocities exceeding "2 volts" scarcely appear at all in our experiments, while smaller velocities appear in a very rapidly increasing proportion [22].

24. Two oppositely directed cathode ray beams in the same space do not interfere with one another.—It is now established that the zero point $U = E = 0$ of the directly observed action U corresponds to the potential difference for which the emitted quantity is equal to the quantity produced (from the other plate) by reflected light and coming into the plate. Rays going out and rays coming in here traverse the same space in opposite directions[23]. This would not be possible if the electricity in motion filled the entire space continuously; for any given volume element can have a velocity

in only one direction at a time. We can, therefore, use this phenomenon to demonstrate the existence of an intimate structure of the electricity here present in motion[24].

[166]

25. The initial velocity is independent of the intensity of the light—the question is, whether the velocity of distribution depends upon the intensity of the exciting light and in particular whether the larger initial velocities will not make up a higher proportion of the whole at higher light intensities; one would expect an affirmative answer to this question, provided that the kinetic energy of the emitted electrons is derived from the force of the exciting light.

It was to be ascertained whether the trend of the curve Y or U changed with the intensity of the light. I paid particular attention to the zero point of the latter curve $U = 0$; this point is favorably situated for this purpose and can be located with greater accuracy than any other point of the curve. It is necessary only to change the potential difference between U and E until we reach the value $X(U = 0)$ where the electrometer, connected either to U or E, remains at rest in spite of the action of the light. The results given in Table X were obtained in this way; the value was often obtained to hundreds of volts by interpolation between points at which the electrometer moved slowly in one direction and in the other. Yet another way is available to determine the zero point. If starting from the potential difference zero we allow the light to act long enough on U, the desired potential difference $X(U = 0)$ is established of itself and can be read on the electrometer when it comes to rest. However, this reading requires, when the insulation is not quite perfected, a correction which is hard to determine; I, therefore, abandoned it in favor [167] of the two others.

Zinc Spark	17.4	2.86	—1.00	—0.97	

In the table we observe, it is true, small differences between associated values of $X(U=0)$ and $X(E=0)$ which indicate a slight escape of electricity from between U and E (17 Stage 3; 20); but not the slightest dependent of one or the other of these quantities on the intensity of the light. Note in particular that within each group the runs are arranged in the order of decreasing intensity as we see in Column 3 (14). With the carbon arc light the intensity varies in a ratio of about 70 to 1. The value of $X(E=0)$ is not changed by as much as one per cent. This means, as we see from the trend of Y (Figure 2 and Table VIII), in the vicinity of $U=E=0$, that the number of electrons having an initial velocity in excess of 1.06 volts is not increased [168] by as much as 5% when the intensity is increased 70 fold; although this number is in itself very small, only .0057 of the total number.

Similar experiments with the same result when carried out with aluminium plates U and E (cf. 34) showed that the intensity of the carbon arc light was here varied in the ratio of about 1000 to 1 without sensible change in the zero point.

26. It is seen directly from Table X, and from Table VI, VIII, and IX, and Figure 2, that different kinds of light give different initial velocities. With zinc arc light large initial velocities are present in very much smaller proportion than with carbon arc light[25]; spark light lies between the two. This last light, while actually shining is far the most intense of all (15) from which we see again that intensity and initial velocity have no connection with one another.

27. Polarized light.—When light from the zinc spark falls under an angle of 58° upon the front surface of a plane quartz plate, which is cut perpendicular to the optic axis blackened on the rear surface, the ultra-violet part of the reflected beam is almost completely linearly polarized. This was verified with a second identical quartz mirror as analyzer. When the mirrors were parallel to one another, the twice reflected beam produced a brilliant green fluorescence on uranium glass and blue fluorescence on flint glass; these were almost completely extinguished when a glass or mica plate was inserted in the path of the beam or when the mirrors were crossed.

[169]

The polarized light was used in two different orientations; in case A, the electric vector was parallel to the surface of U, in case B it was perpendicular to the former direction and made the largest possible angle with the surface of U, to wit, 45°. In case A, the electric vector is perpendicular to the plane of the paper in Figure 1; in case B, it lies in this plane [26]. The results are as follows:

TABLE XI.

Zinc Spark Light, Polarized. Distance UE = 10 mm.

	Zero-point X(E = 0) volts	Total Emission E(+ 100) coul./sec.
Case A	—0.95	0.16×10^{-10}
Case B	—1.0	0.17×10^{-10}

There is consequently no certain difference between cases A and B either as regards the initial velocities (second column) or as regards the quantities emitted (third column)[27].

28. To the previous results (25, 27) the following may be added. People have learned to regard the strong absorption of light as a resonance phenomenon located in the molecules or atoms of the absorbing body. As a matter of fact even in our experiments action is not produced by light of every wave length; we find that a transparent leaf of mica or piece of glass held in the path of the light destroys all the effect. We may [170] consider that the same electrons which the light causes to be emitted have been vibrating under the influence of the light just before the emission and at that time must have been bound to the atoms by forces. If we assume as the simplest case that those forces are independent of time and are such that linear light vibrations excite linear resonance vibrations[28] the amplitude of these vibrations will increase until the accumulated kinetic energy exceeds the maximum potential energy that can be derived from these forces. The electron will then leave its atom with the excess kinetic energy. This excess, which represents that part of the initial velocity due to the light must have been acquired during the last half or whole resonance period. Hence, it must increase with the intensity of the light, but since we found that this was not so in actuality (25) it follows that the assumption of simple resonance motion does not account for the phenomena. We might assume more complicated motions in the interior of the substance or adopt the hypothesis which, for the present,

seems most appropriate that the initial velocities of the emitted electrons do not come from the energy of the light but from violent motions already existing inside the atoms before the illumination began; so that the resonance motions merely set them free.

Even the magnitude of the observed initial velocities, for example, "3 Volts" ($= 8 \times 10^7$ cm/sec) for aluminium (34, 36), contradicts the assumption that they can have been absorbed during half a period or even during several half periods of light of ordinary intensity potential differences of three volts are not found in such light. Furthermore, we found that the normal component of the initial velocity was not clearly altered, when the normal component of the electric vector of the incident [171] light was reduced to zero (Case A, 27).

29. **When the outside field is accelerating the field strength determines the action.**—Stage 4 of the phenomenon (17) was characterized by the fact that in spite of an accelerating outside force the emission was not yet complete. We investigate first the influence upon the phenomenon of changing the distance between the plates U and E. Table XII contains the relevent results which are graphically represented in Figure 1.

TABLE XII

P.D. between U and E X Volts	Charge leaving U; U.				
	UE = 5 mm.		10 mm.	25 mm.	40 mm.

* With correction for conduction: See Note to (12).

[172]

While in the case of the retarding forces the action depended only on the potential difference between U and E (21), we find here that it depends not only on the potential difference but also on the distance between the plates; approximately, however,—as we see from the graph—in such a way that the quotient of the two magnitudes, that is, the strength of the approximately homogeneous field between U and E, determines the action. The principal deviations from this rule occur when there is no outside force (last line of Table XII) when the action should be the same at all distance UE. It was suspected that in this case the glass walls which surround the plates had become charged by the rays which had escaped sidewise (17, stage 4) and thus caused disturbing outside forces. This was verified by repeating the experiments, the glass wall being covered with a metal sheath (EH, Figure 1) which was blackened like U and E and had an opening to let the light through. In order not to destroy the approximate homogeneity of the electric field between U and E, the potential of the sheath was always (except where otherwise stated) kept equal to the arithmetic mean of the potentials of U and E; this was for all distances UE greater than 5 mm. For 5 mm. the sheath and the plate E were connected together and hence at the same potential. The following results were obtained.

TABLE XIII.

Sheath in tube: Carbon arc.

P.D. between U and E X Volts	Charge leaving U; U.			
	UE = 5 mm.	10 mm.	25 mm.	40 mm.

1.96	0.852	0.909	0,865	0.799
0.97	0.831	0.864	0.781	0.751
—0.080	0.671	0.684	0.605	0.669

Mean Value U (— 0.080 Volt) = 0.645

* Corrected for conduction: See Note to (12).

[173]

Within the limits of accuracy, the emission at the potential difference zero or 0.030 no longer depends on the distance UE. Furthermore, the mean value of this emission 0.645 is much higher than any of the values obtained earlier with an uncovered glass wall and no outside force (Table XII, last line) which confirms the previous supposition about the influence of the glass wall[31].

If we arrange all the observed measurements on U in Table XIII in the order of diminishing field strengths, we obtain the series of steadily decreasing numbers in Column 2 of Table XIII-a; there is no relation between these numbers and the adjacent distances UE and the principle announced at the head of this paragraph (20) is verified. In this table the three values, numbers 2, 4 and 8, are from Table XII, Column 3; they fit in so well as to show that when the distance UE is equal to 5 mm. and the accelerating P.D. is greater than 0.5 volt there is no sensible influence of the glass walls[32]. The only values that do not fit in this series are numbers 3 and 6 taken from Column 2 of Table XIII. Re-

TABLE XIII-a.

Field Strength 5X/UE Volts/5 mm.	Charge leaving U	Distance UE	Number
20, 12.5, 10, 20	1.00	25, 40, 10, 5	1
2	0.95	5	2
1.96	0.852	5	3
1	0.90	5	4
0.98	0.909	10	5

0.12	0.751	40	14
0	0.645	Average	15

lative to these, note that they were taken immediately after U had been freshly blackened, while all the other values relate to surfaces which had been blackened one or several days before. I also observed values about 10% too low for small accelerating forces at another time, when the black had been applied immediately before. For what follows, only values obtained with old sur-
[174] faces were taken into account.

30. Only the value of the field strength at the illuminated surface affects the result. — Up to this time the electric field between U and E was nearly homogeneous; now, we compare such a field (a) with an inhomogeneous field (b). The potential difference between U and E was in both cases the same (4 volts accelerating); but while in case (a) the sheath has the mean potential (as always up to now), in case (b) it has the potential of U. The field is, therefore, in the second case stronger on the side towards E, weaker on the side towards U.

	POTENTIALS			
Case	U	Sheath	E	Charge leaving U
a	0	2 Volts	4 Volts	0.908
b	0	0 "	0 "	0.796
		UE = 25 mm.		

[175]

We see that the action in the two cases is markedly different, being smaller when the field at U is weaker. Note that in case (b) no charging up of the sheath could be detected, so that it can not be supposed that there was a direct action of the diminished potential of the sheath.

31. According to the preceding work (29, 30) the increase in the effect as the accelerating outside force increases—which we described as Stage 4 (17)—can

be regarded as a consequence of a special retarding force of electrical nature acting only very close to the illuminated surface. The presence of such a force is also indicated by the phenomenon that a negatively charged substance does not of itself lose any of its charge in a vacuum (4, Note 2) although its own electric field tends to drive the charge out of it, and the vacuum is capable of taking it up (3).

We will consider this force K, measured in volts per cm. as a function of the distances from the boundary of the body. The largest distance in which the force is still sensible, is represented by σ, and

$$\int_{\rho}^{\sigma} Kds = \int_{\rho}^{\alpha} Kds \text{ by } \Pi$$

wherein $\rho < \sigma$ represents a constant length of the order of magnitude of the intermolecular distance inside the substance. II signifies the diminution in velocity undergone by the electrons leaving the body because of the force K. The velocity remaining after the electron has traversed the field of the force K is the directly measured initial velocity (23) which we shall call the "outside initial velocity"; the sum of this and II volts is to be called the "inside velocity".

Now, let the function F (P) represent the number of electrons having an inner velocity greater than "P". This function has the same significance for the inner velocities as Y(—P) in (23) for the outer velocities. We have ($F(0) = 1$, $F(\alpha) = 0$, $F'(P)$ negative.

[176]

If now there is an outside retarding electric force of absolute magnitude X Volts/S cm., the quantity of charge that escapes will be represented by $F(II + X)$. If the force is accelerating it is to be subtracted from K, and since K may have high volume at small distances from the surface of the substance, there will be retarding force from the surface out to a certain distance T and accelerating force beyond this distance. T is a function of X/S; for $X = 0$ we have $T = \sigma$, otherwise $T < \sigma$. The electrons which are not turned back by the time they reach T will not return to U at all but will be definitely emitted. The number of these electrons is therefore.

$$F\left[\int_{\rho}^{T}\left(K-\frac{x}{S}\right)ds\right]$$

the integral, which like T is a function of X/S is designated by $\Phi(X/S)$. The nature of this function is entirely determined by the law of force $K(s)$; in any case we shall have from what has gone before

$$\Phi(0) = II. \qquad \Phi(XIS) = -1$$

Therefore, the function Y (22) representing the observed effect minus that due to the reflected light, is represented for the retarding potential difference of absolute magnitude X by

$$Y(-X) = F(II + X)$$

and for accelerating potential difference X by

$$Y(X) = F\,[\Phi(X/S)] \text{ where } S = UE$$

when the outside force is zero, either of these equations gives,

$$Y(\pm 0) = F(II)$$

The shape of the curve which represents Y as a function of X is determined for retarding X by the distribution of velocities alone, for accelerating X by the distribution of velocities and the law of force. The curve, therefore, consists of two branches of entirely
[177] different type, joining at $X = 0$. The slopes of the two branches are given by

$$dY/dX = -F'(II + X) \quad \text{for the negative branch.}$$

$$dY/dX = F'\left[\Phi\left(\frac{x}{S}\right)\right].\Phi'\left(\frac{x}{S}\right)\frac{1}{S} = -F'\left[\Phi\left(\frac{x}{S}\right)\right]\frac{1}{S}$$

for the positive branch

for $X = 0$ where the two branches meet we have on the negative side the derivative $-F'(II)$ and on the positive side the derivative $-F'(II)\frac{\sigma}{S}$. The two branches, therefore must form an angle with one another at which the slope alters discontinuously in the ratio of $\frac{S}{\sigma}$. When σ is small compared to the distance S between the plates as we assumed in the previous experiments, the positive branch at $X = 0$ must be nearly horizontal in spite of the steepness of the negative branch as found by experiment at this place.

32. These deductions from the hypothesis of a retarding surface force, acting within a narrow layer, have been confirmed by thorough investigations in the vicinity of value zero of the outside force. A galvanometer was substituted for the electrometer, since the latter gives only the mean value of the effect over the range of potential difference corresponding to its deflection and does not accurately reproduce singularities at some particular value of the P.D. The plates U and E were encircled by the sheath which had the mean potential (29); a magnetic field was impressed from the coil SS. Figure 1 (18), so that only the axial component of the electric field was used. In the following table each number is the mean of from 15 to 20 galvanometer readings, the current being alternately in opposite directions.

TABLE XIV.

[178]

In the graphical representation, Figure 3, the scale along the axis of the abscissa is very much larger than in Figure 1, Plate 1. The distances of the observed points from the curve lie within the probable error [34], so that there is no doubt about the discontinuity in slope or the general agreement with the electrometer observations. The discontinuity, however, appears at 0.04 volts instead of at 0 volts, which may be interpreted as meaning that the two carbon surface U and E had an intrinsic potential difference of 0.04 volts[35]. The discontinuity appeared likewise with aluminium and platinum plates which were not blackened (34) (compare

Plate 1, Figure 2) and similar small displacements from zero were observed.

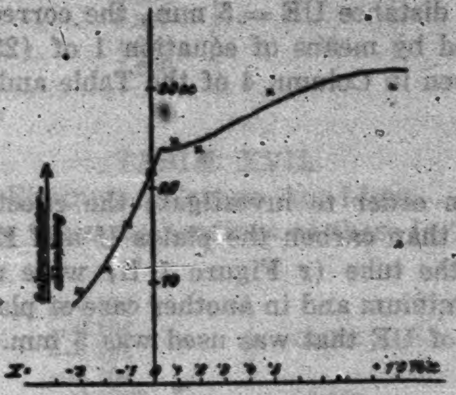

Fig. 3.

33. The action with carbon over the entire range is given in the following Table. Some of the previous observations have been averaged together and some new

ones added where needed (compare Column 3). From the observed effect U (Column 2) which is everywhere reduced to distance UE = 5 mm., the corrected effect Y is computed by means of equation 1 of (22)[36], and is [179] given in Column 4 of the Table and in Figure 2 of Plate 1.

[180]

84. In order to investigate the effect with other substances than carbon the plates U and E, the sheath (29) and the tube (r Figure 1 B) were made in one case of aluminium and in another case of platinum. The only value of UE that was used was 5 mm.; the results follow:—

It is to be noted that when aluminium was used the apparatus was put together and pumped out immediately after polishing of the metal surfaces with emery. Observation began when the limit of efficacy of the pump had been reached about an hour after the polishing. At that time the magnitude of the effect was still diminishing and continued to diminish for about three-quarters of an hour, or about as long as the pump was still removing bubbles of gas from the apparatus; thereafter the effect remained unchanged for ten days. The data in the table referred to this latter state. The discontinuity of the slope of curve U was located at 0.273 [182] volts; it was assumed as before (32) that the potentials of the electrodes U and E differed by that amount when they were in metallic contact and, consequently, the scale of potentials was displaced by 0.273 volts giving the final column of the table[39].

In the case of platinum, which was also freshly polished just before the observations, the discontinuity was at 0.12 volts; the scale of potentials was displaced correspondingly to give the last column of the table. Figure 2 of Plate 1 shows $Y(X)$ for all three substances, carbon, aluminium and platinum.

35. "Inside" Velocities. — As we saw in (31), the negative branch of $Y(X)$ gives the values of the velocity distribution function F for all values of the inside velocity greater than "II". We can form a judgment on the course of the function for velocities smaller than "II" from the positive branch of Y. The slope of this branch increases, as Figure 2 of Plate 1 shows, very rapidly as X increases from zero (where it is nearly zero). Since T can only decrease as X increases, F' must increase according to equation 2 of (31). Consequently, as we go towards the right from $X = 0$, the function F will increase at a constantly increasing rate, as is indicated by the dotted curve oa in Figure 2 of Plate 1 for the case of platinum. As X continues to increase, Y' rapidly approaches zero; this value is very nearly attained by $X = 10$ volts or $X/S = 20$ volts/cm. for all three substances; Y is then very nearly equal to one, as Figure 2 of Plate 1 and the Tables show. Equation (2) admits two possible forms for the function F. Either (A) T is already zero, so that F' can continue to have high values as far onward as $F = 1$ (aA in Figure 2 of Plate 1); or (B) T is not yet zero, so that [183] F' must become zero (aB in Figure 2 of Plate 1). Case (a) would signify that the integral II must be very small, scarcely 0.1 volts, and that most of the inside velocities of the electrons are vanishingly small. However, experiment contradicts the assumption made for this case: to wit that T is nearly zero when the force is 20 volts per cm. and, consequently (31) the force K does not have higher values than 20 volts per cm. anywhere. Outside forces opposed to K did not extract any

negative electricity from aluminium surfaces in vacuo even when they reached a magnitude of 45,000 volts/3.6 cm. (4, Table 1, Note 2). Consequently, we regard case (A) as excluded and case (B) as the true one. This means that by far the greater part of the electrons liberated by the light in the interior of the substance already possess there a definite relatively large velocity, which is to be designated as the most probable inside velocity of an electron; both smaller and shorter values of the velocity occurred, but only in a proportion which is small and diminishes rapidly to zero as the deviation from the most probable velocity increases[40].

We must take account of the fact that our data relate only to one component of the velocity, that perpendicular to the surface (23) while the existence of components in other directions has been demonstrated (8, 18, 19, 20, 29). As respects this, I have carried through computations on the basis of the observed distribution of the normal components of outside velocity as given in Tables 15 to 17; the results of these computations agree neither with the idea that there is a single definite inside speed and that all directions are [184] equally probable, nor with the idea that the inner velocities are distributed according to Maxwell's law[41]. The magnitude of the most probable inside velocity, corresponding to the greatest slope of F, seems for each of the three substances investigated not to differ very much from the corresponding value of "II". Our experiments permit us to say nothing about this last magnitude, except that in each of the three cases it must be greater than about 0.1 or 0.2 volts (for platinum, the abscissa of (B), Plate 1, Figure 2).

36. The following data gives values of the outside velocities for carbon arc light taken from the original data given on a large scale in Figure 2 of Table 1; the velocities are expressed in the customary units, centimeters per second; ε/μ is set equal to 10^{+7} C.G.S. units.

TABLE XVIII.

Escaping with Assistance of outside Force	.28	.21	.35
Total	1.00	1.00	1.00

[185]

The predominance of relatively small outside velocities, already mentioned in (23), for carbon, is found with aluminium and platinum as well. Platinum, however, gives more of the larger velocities than carbon, and aluminium more than platinum.

37. I must not fail to mention the influence that the roughness of the surfaces employed must have had on the results. The carbon surfaces were naturally rough, the metal surfaces were roughened by the polishing with emery. Since the initial velocities have considerable tangential components (8, 18, 19, 20, 29), a part of the emitted electrons must have been caught by the projections of the rough surfaces. This influence of the roughness cannot have had any effect on the observations for large retarding or large accelerating forces; it would come to light only in a lowering of the values of U and Y in the vicinity of zero potential difference. With smooth surfaces we should expect a more rapid rise of the negative branch and a less rapid rise of the positive branch of Y. Such a change indeed is necessary to avoid a contradiction which is found to exist between the form of Y as experimentally determined and the assumption (made for smooth surfaces) that the force K acts within only a narrow layer. The general conclusions respecting the velocity distribution (35, 36), however, are not affected.

38. To account for the surface-force K (31) there are three possibilities:

(a) Electrical double layers on the surface.

(b) A specific attraction between electricity and the conductor, something as Helmholtz assumed to explain contact potential differences (8).

(c) The undoubtedly present electrical force between the escaping electrons and their electrical images in the surface.

In cases (a) and (b) the force would depend upon [186] the nature of the conductor; in particular we should expect a marked difference between the value of the integral II for aluminium on the one end and its values for platinum and carbon on the other, since the last two are far from the first in the contact potential-series. If the inside velocities are the same in each case the negative branch of the Y-curve of one would appear to be displaced horizontally relative to those of the others. But this is not the case, the displacement of platinum relatively to carbon for small values of Y(—X) is greater than that of aluminium relatively to platinum, while for large values of Y(—X) carbon is closer to aluminium than it is to platinum (Plate 1, Figure 2). However, II could vary from one substance to another without having the above consequence, if — making assumption (b) — a greater attraction between the substance and the electrons went with a greater inside velocity of the electrons; but, without further knowledge the converse would be more probable. It can, therefore, be stated, that no attraction between electricity and the substances tested differing for the different substances, can be detected. Hence, if we are to assume such an attraction (as electro-chemical reasons lead us to) it appears from our experiments that we must assign it a sphere of action smaller than the intermolecular distances in the substances investigated by us. In this case the attraction would contribute nothing to the integral II, and then it would have nothing to do with the appearance of contact potential differences at the surfaces of metals in contact.

It seems indubitable that electrical double layers exist at the surfaces of conductors in air[44]; nothing is known as to whether they persist in vacuo. One of the most powerful means of removing adherent layers of gas from a metal plate is to use it as cathode in the glow [187] discharge. I did this with the same platinum plate as was used before hand in (34). The apparatus was filled with hydrogen[45]; after this a storage battery with many cells was applied, and the platinum plate, acting as cathode, kept covered with negative glow for six hours; the opposite platinum plate E was the anode. If this had caused a decrease of II, this should have been recognized through an increase in Y(0). Nothing of the sort appeared; Y(0) was found equal to 0.5 at the end of the process after the apparatus had again been evacuated, which was a smaller value than before. Note also, that, to explain the phenomena, we would have to assume that all three substances, including platinum, after the above process, had a double layer with the negative charge destroyed.

About the force (c) we would say not merely that there is no doubt that such exists according to present-day knowledge, but even that its properties correspond directly to our observations. This force has at distance (S) the magnitude.

$$K = \frac{300e}{4S^2}$$

wherein small (e) represents the charge of a single independently mobile electron equal to 6.6×10^{-10} electrostatic units[24]. Hence, we derive the values

K(s) equals	When s equals	$II = \int_{\rho}^{\alpha} Kds = \int_{\rho}^{\sigma} Kds$	When ρ equals
$.0005 \frac{\text{Volts}}{\text{cm.}}$	0.1 m.m. $= \sigma$	0.5 volts	$10^{[illegible]}$ m.m.
5	.001 m.m.	5. volts	$10^{[illegible]}$ m.m.
5.10^6	.10[illegible]		

This force, therefore, satisfies the condition of becoming vanishingly small at distances which are small compared to plate-to-plate distances UE, but which compare with the intermolecular distances; furthermore, [188] it assumes, at distances which are still not below molecular size, values so great that we can account for the fact that unilluminated and highly charged conductors in vacuo lose none of their charge (4, Plate 1, Note 2); the value of the integral exceeds the lower limit indicated by our experiments[35].

EXPERIMENTS IN A GAS-FILLED SPACE

39. In earlier experiments I showed that cathode rays make air electrically conducting[46]; we shall now investigate to find whether rays of any speed do this, or whether rays moving more slowly than a certain speed are unable to do it as is indicated by the unipolar character of the photoelectric effect (9, 11). The apparatus used (Figure 4) will now be described. U is the plate to be illuminated; opposite it is the surface E, the central part of which consists of fine wire gauze (wires 0.1 mm. thick; meshes 1 mm. square); beyond the gauze is the aluminium ring R. U, E, and R are insulated from each other, so that two arbitrary electric fields can be established on the two sides of E; these

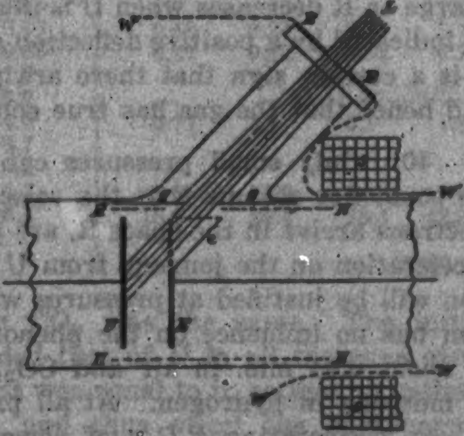

Fig. 1.

fields are made independent of each other by the tube ee, which is connected with E, closed at the right-hand end by a gauze, and perforated at g to allow the light to pass through. E is earthed; everything between U and E, including the gauze, is well blackened. The glass [189] tube surrounding the whole can be filled with any gas and the pressure measured. The coil SS, as before, prevents sidewise escape of electrons, so that nearly all the emitted electrons go to R, no matter what the magnitude of the accelerating force between U and E. The zinc arc was used.

The experiments were performed as follows. By changing the P.D. between U and E we can regulate the velocity of the rays which pass through the gauze to R; this velocity is always known from the preceding experiments. It is now to be ascertained whether, when the rays are absorbed in the gas around R, negative ions only are produced, or positive ones as well. Only in the latter case would there be true, as distinguished from unipolar, conductivity of the gas. R was therefore connected with the electrometer and negatively charged, together with the casing of the electrometer. If the charge on R decreases when U is illuminated—which will be indicated by a positive deflection of the electrometer—it is a certain sign that there are positive ions present and hence that the gas has true conductivity.

40. Only small pressures can be used; otherwise we could not assume that the velocities with which the electrons arrive in the space R, are produced by uniform acceleration on the journey from U to E. This assumption will be justified at pressures when further rarefaction has no influence on the phenomenon. This occurs at about 0.04 mm. in air and CO_2, at about 0.06 mm. of mercury in hydrogen. At all pressures below these values, accelerating P.D.'s of eleven or more volts between U and E, give large positive electrometer deflections at R; P.D.'s of eight volts or less give only very small deflections, as Table XIX shows in detail. The existence of a limiting speed is thus definitely demon-

[190] strated47); its magnitude will be discussed later (42).

The behavior in CO_2 was the same. The initial potential of R exceeded that of U in all the runs given in the table, or at least was equal to it, so that no cathode rays could reach R and thus affect the electrometer directly; 20 volts was the potential of R, except in one case specified below. Higher potentials up to more than 100 volts, gave no markedly higher electrometer deflections, whence it follows that the smaller P.D.'s were high enough to bring to R all the positive ions produced beyond E; use is made of this result below (45). If on the other hand the potential of R was lower than, or even equal to that of U, and that of U was less than [191] 11 volts, the electrometer connected to R gave a negative deflection. This shows that even when the potential of U was low, cathode rays passed through E into the space around R; so that the absence of positive ions at these potentials cannot be ascribed to absence of cathode rays. For example, a strong negative deflection was observed when U = 10 volts and R = 10 volts, both negative relatively to E, in air of 0.04 mm. pressure; also when U = 0 to 20 volts negative and R = 0 volts in air at .04 and .004 mm. and in hydrogen at .002 mm. pressure.

---

* This table crossed out in original Exhibit.

41. Free paths of the electrons. — Above the limiting pressures described in (40), definitely higher potentials than 11 volts were required in order to produce positive ions in the region R. This indicates that the electrons do not undergo uniform acceleration between U and E, or that their mean free path in the gas has become equal to the distance UE = 14.5 mm. The mean free paths of the gas molecules at these pressures are 1.9 mm. in air, 1.2 mm. in CO_2 and 2.3 mm. in hydrogen [49]; the free paths of the electrons, at their present velocities of one to ten volts[50], are some ten times as great as those of the gas molecules, or some twice as great as those of vanishingly small, rapidly-wearing bodies which cannot penetrate gas molecules[51]. The free paths of the rays previously investigated by me, of about 100 times this speed, were much greater[52]. Thus, in oxygen or hydrogen at 40 mm. pressure, such rays travelled 5 or 10 cm. without being much bent aside [192] or diffused[53], and it is proved[54] that the magnitude as well as the direction of the velocity remains the same over this distance. The free paths of the molecules of the gas in which this occurs are only .00019 and .00034 cm. respectively, so that the electrons have free paths 30000 times and 5000 times as long, respec-

tively, as small particles which cannot pass through gas molecules. This confirms the principles previously discovered for a small range[55] that cathode ray beams are less spread out and the rays less absorbed in gases, the smaller their magnetic deflection (by a given field); for this principle may be restated as follows[56] the free paths of the rays are greater, the greater their velocity.

The fact that free paths of the above lengths are possible while markedly longer free paths are not—considering the spreading-out of beams and the absorption of cathode rays, and the limiting pressure found in the present work—appears to indicate that the molecules and atoms of matter are structures made up of minuter parts with many interspaces and many possible kinds of internal motion; the structure as a whole being impenetrable to another similar atom. However, the study of the questions which have arisen since my earliest publications on cathode rays and since the establishment of the recent hypotheses, will not be profitable until further observations on rays of various speeds are made.

42. The value of the limiting speed, above which positive ions are formed, can be estimated from Table XIX in the following way. Plotting the accelerating P.D., x, as abscissa, and the electrometer-deflection, 2, as ordinate, we obtain curves which from $x = 0$ to (?) 8.5 volts run nearly horizontal and close to the axis of abscissae; then, within the interval $x = 8.5$ to 11 volts, turn sharply upwards and finally run steeply and almost linearly upwards; the last part of the curve points in the direction away from the point $X = 10.5$, $2 = 0$; the several runs given in the table agree very closely over all this range. This form of curve may be explained on the hypothesis that the number of ions produced by each electron is proportional (within the range of observation) to the excess of the velocity of the electron over the limiting velocity[57] and is zero when there is no such excess. Let N (v) dv represent the number of electrons which traverse the gauze with a speed between $v = \frac{1}{-2} dv$

and $v + \frac{1}{2} dv$; V the limiting speed, and C a constant; then the deflection of the electrometer would be

$$z = C \int N(v) . \quad (v - V) \; .dv$$

the integral extending over all values of v which are greater both V and x. Since $N(v) = Y'(x - v)^{58)}$, (23), we obtain

$$z = C \int_{\sigma}^{V-x} Y(-X) \, dX \quad \text{for } x \leqq v$$

$$z = z(x = V) + C(x - V) \quad \text{for } x > v.$$

$Y(-X)$ is to be taken from Table IX with the aid of equation (1), or from Figure 2 (23); it is very nearly zero for all values of X between a and 2.5 volts, from which onward it increases. If then we set $V = 11$ volts in equation (3), Z varies quite in the way observed and
[194] described above; for it remains nearly zero until $V - x = 2.5$ volts or $x - 8.5$ volts, then increases, and from $x = V = 11$ volts on becomes linear once more. The desired limiting velocity is then 11 volts, or in the customary units 1.5×10^8 cm/sec. or $\frac{1}{200}$ of the velocity of light; the corresponding kinetic energy is $e.V. 10^8 = 2.4 \times 10^{-12}$ ergs, e being taken as 6.6×10^{-10} electrometer units.

43. It must be pointed out that the same value of the limiting speed is found whether the apparatus contains air, hydrogen, or CO_2, or is kept pumped out by running the mercury pump continuously (cf Table XIX, last column). The formation of positive ions in the last case will be ascribed to the residual vapors (12); it may even be assumed that they were formed from these residual vapors in every case, for Table XIX displays no markedly greater deflections for gas filled than for evacuated apparatus. The limiting speed for the gases would then be higher than the one here given. But since a given number of electrons can produce only a given number of ions, we may for the time being also make the contrary assumption: that the limiting speed is the same for the residual vapor and all three of the

investigated gases, and perhaps for all substances whatsoever. In any case the result remains, that speeds less than the given limit make neither the investigated gases nor the residual vapors conductive.

44. As regards the first part of the present investigation (22-38) this last proved that the conductivity of the residues of gas or vapors played no part at any small accelerating potential, but even at the higher accelerating potentials where conductivity appears, its effect is only slight in comparison to the direct transport of electricity by cathode rays, as will be shown in the following.

45. Number of ions produced.—Suppose the potential difference UE to be 12 volts; then from the corresponding figure in the last column of Table XIX and [195] the capacity of the electrometer, it may be computed that the quantity of electricity carried by the ions formed in one second is .039 times 10^{-10} coulombs, while the charge on the electrons which produced these ions is 25×10^{-10} coulombs[59]. The ratio of the number of ions formed to the number of electrons is here ,0016; it is equal to .23 when UE is equal to 100 volts (according to Table XIX). These ions were formed in the space ER (Figure 4); the electrons which produced them enter through the gauze E with the velocity corresponding to the potential difference UE and were gradually slowed down at an almost uniform rate as they traversed the distance ER = 20 mm., turned around in the vicinity of R[60] and returned over the same path with the same velocities; thus, they traveled a distance of 40 mm. with nearly zero velocity at one end and the velocity corresponding to the potential difference UE at the other. We should, therefore, expect to obtain the same number of ions in the regions UE if the potential difference between U and E were the same and the distance between them 40 mm.; and if the distance were $\frac{1}{m}$ times as great, we should expect m times as many ions. The following table of corrections was made up in this way. The values for other potentials UE being found by linear interpolation (according to 42); the table gives the

quantity by which the charge lost by U is to be divided in order to allow for the loss due to conduction.

TABLE XX.

Distance U E

P.D. UE Volts	5 mm.	10 mm.	25 mm.	40 mm.
12	1.00	1.00	1.00	1.00
20	1.00	1.00	1.01	1.02
100	1.03	1.06	1.15	1.23
200	1.06	1.12	1.30	1.46

46. The unipolar character of the photoelectric [196] effect, which seems to be established without doubt in ordinary air and for all lower pressures, is explained—as already mentioned in (11)—by the magnitude of the limiting velocity (42) which far exceeds the initial velocity of the electrons driven out by the light (25, 26, 36). The action is unipolar even in the case of the alkali metals, photoelectrically the most active of substances, so that even for them the initial velocities must be less than 11 volts. It is different with the so-called radio active substances which even when not illuminated emit extremely small quantities of electricity but with extremely high initial velocities. Substances of the same kind with rays having initial velocities less than 11 volts might exist without being discoverable by the convenient present method.

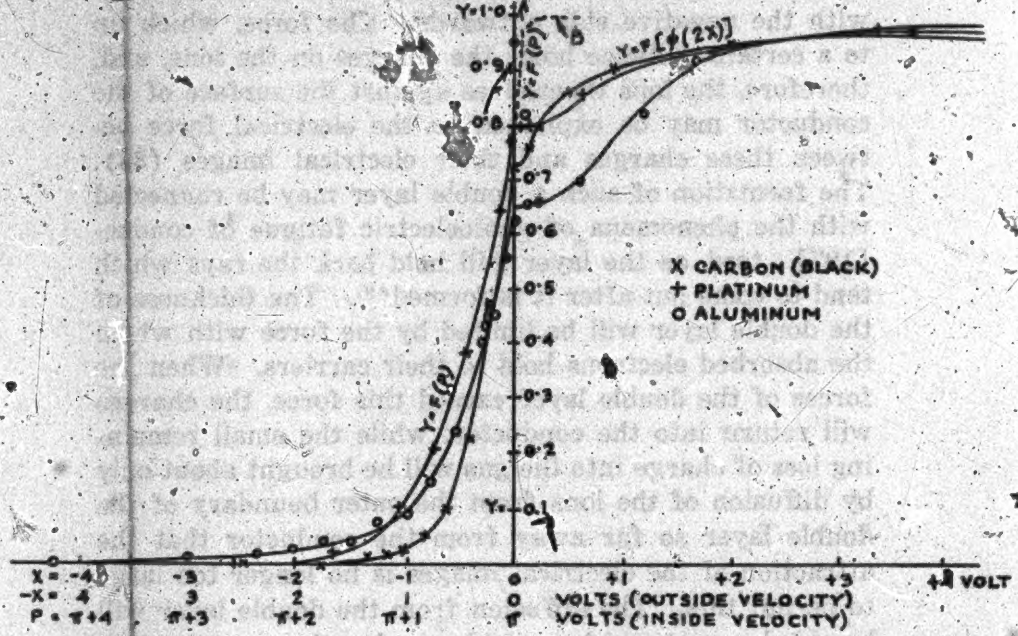
47. As regards the photoelectric effect in gases at atmospheric pressure it seems to me that no adequate explanation has yet been given for its astonishing smallness. For example, it is seen from Table II that when we have aluminium surfaces in air with an applied outside accelerating force of 83.5 volts per cm. not ¼ of 1% of the emitted electricity gets completely away; and even with a force of 2780 volts per cm. only 4.7% escapes. The following considerations are suggested by the results of the preceding work and can even satisfy a quantitative test on the basis of the experiments already performed; this is shown by computations which I am not publishing at present because I have no experiments to report. — Since, when we have a dense gas surrounding the surface, the emitted electrons must be absorbed in

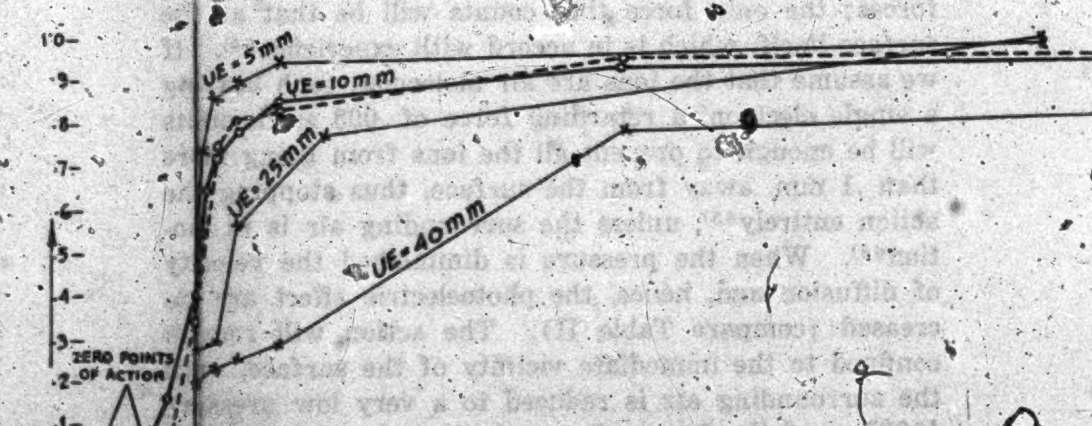
the immediate vicinity thereof (41), negative ions must accumulate there and thus rapidly form a double layer with the negative side outwards. The force, which up to a certain distance holds the charges on the ions, and, therefore, the ions themselves against the surface of the conductor may be explained as the electrical force between these charges and their electrical images (38). The formation of such a double layer may be connected with the phenomena of photoelectric fatigue of conduc-
[197] tors, as the layer will hold back the rays which tend to come out after it is formed[63]. The thickness of the double layer will be limited by the force with which the absorbed electrons hold to their carriers. When the forces of the double layer exceed this force, the charges will return into the conductor, while the small remaining loss of charge into the gas will be brought about only by diffusion of the ions from the outer boundary of the double layer so far away from the conductor that the attraction of the electrical images is no longer too large to permit this. The diffusion from the double layer will be aided or opposed by outside accelerating or retarding forces; the only force that counts will be that at the surface itself, which is in accord with experience[64]. If we assume that the ions are air molecules, each bearing a single electron, a retarding force of .003 static units will be enough to prevent all the ions from going more than .1 mm. away from the surface, thus stopping the action entirely[65], unless the surrounding air is in motion[66]. When the pressure is diminished the velocity of diffusion and, hence, the photoelectric effect are increased (compare Table II). The action will remain confined to the immediate vicinity of the surface, until the surrounding air is reduced to a very low pressure
[198] and the free paths reach the values of (41); in this state, when there is a decided accelerating force, the conductivity imparted to the air will aid in the manner indicated in (9), so that the loss of charge will be even greater than in vacuo[67].

Kiel, Middle of March, 1902.

Received March 17, 1902.

Defendant's Exhibit No. 10-A





NOTES.

1. P. Lenard, Wiener Sitzungsberichte, 108, IIa, 1649, (1899); also Ann. Phys. *2* 359 (1900).—Cf. also the somewhat later work of E. Merritt and O. M. Stewart, Phys. Rev. *11* 230 (1900).
2. In this respect it resembles the third means of production since discovered—i.e., by radioactive substances.
3. To facilitate reference to the earlier paper (l.c.) its numbering of tables and paragraphs is continued here.
4. P. Lenard, Ann. Phys. *51* 240 (1894).
5. Conductivity of the space made its appearance during the work, but not at P.D.'s below 8 volts (44). When necessary to accuracy, a correction was made to allow for it; data so corrected will be indicated by asterisks. For the way in which the correction was computed see (45) and Table 20.
6. The effect was proportional to the duration of the action; the data will therefore be reduced in some future cases to move convenient values of duration or of capacity.
7. The voltages to be given hereafter, when stated to hundredths of a volt, are the mean voltages during the deflection of the electrometer, obtained by adding half the deflection to the initial voltage.
8. High magnification (with a telescope) and a scale with diagonal rulings enabled us to read tenths of scale divisions directly, and to estimate hundredths.
9. Note that in these runs only U was blackened. E being an old unblackened aluminium surface; but this may be regarded as unimportant for the present purpose.
10. Cf. especially the experiments of Elster and Geitel, Ann. Phys. *48* 625 (1893).
11. Schuster and Hemsalech, Phil. Trans. *193* 189 (1899); Table 10, Fig. 19, and the corresponding text.
12. In connection with our notation, note that "quantity of electricity" always means "negative quantity" and that outside forces are counted positive when they accelerate [outwards] negative electricity coming from E. These conventions correspond to the hypothesis that we have to do with motion of negative electricity only. For example, the negative numbers in Column 3 of Table 5 mean that positive deflections of the electrometer connected to E were observed, i.e., in our form that negative charges were escaping from E.
13. The difference between the actions of the two kinds of light will be discussed later (26).
14. For the subsequent experiment we must think of this sheath as again removed.
15. For ϵ/μ we take 10^7. E. M. U.
16. A. Righi, Mem. Accad. Bologna (4) *9* 369 (1888).

17. A. Righi, Mem. Accad. Bologna (4) *9* 379 (1888).

18. This note inserted in text.

19. Apparently the very refrangible ultra-violet rays peculiar to the zinc arc and the spark are less reflected from the black than are the less refrangible ultra-violet rays of the carbon arc. For the infra-red Kurlbaum finds the reflecting-power of petroleum-black equal to 0.05 which is particularly large (Ann. Phys. *67* 850 (1899).

20. Later on (in 31) it is assumed that the velocity of the electrons undergoes an abrupt finite change at the surface so that inside and outside velocities are to be distinguished.

21. The velocity "P volts" is $\sqrt{2.\ 10^8.P.r}$, where r represents the ratio between the electron-change and the electron-mass, usually called ε/μ [nowadays e/m]. Cf. Ann. Phys. *64* 279 (1898). The quotation-marks will be applied to the voltage-measure of velocity, from now on, only when a misunderstanding might otherwise occur. Electrons having a velocity "V" acquire velocity "V ± S" after passing through a potential difference ± S (Ann. Phys. *65* 504 (1898)]. Note that in these units kinetic energy, not velocity, is measured.

22. For further data on the velocity-distribution, for A1 and Pt as well, see (36).

23. No secondary phenomena whatever being observed; even with A1 and Pt plates, where the backward rays are much stronger than with carbon.

24. Helmholtz was the first (Faraday address, 1881) to emphasize that certain phenomena, especially those of electrolysis, distinctly demand the assumption that electricity has structure; for in electrolysis we find electricity divided into elementary units, always of the same size, each associated with a material carrier. Whether this structure of electricity occurs without the influence of material particles can be determined only by experiments on electricity free from matter, as it is found in cathode rays. In what follows we assume this to be the case, taking the charge found by J. J. Thomson to be associated with material carriers [Phil. Mag. (5) *46* 518 (1898); (5) *48* 557 (1899)] to be equal to that of a single free, independently mobile charge of free electricity.

25. This holds for the effect on carbon (lamp-black). With A1 plates (34) the zero-point for the zinc arc was only about .02 volt below that for the carbon arc; when one of the arc carbons was replaced by an A1 rod the zero-point was not distinctly shifted. The kind of light therefore makes little difference with the initial velocities from A1 as compared to carbon.

26. Previously we had used a piece of quartz cut ⊥ to the optic axis: in these runs it was replaced by one cut || to the axis, in which the direction of the two principal vibrations were parallel to the two directions mentioned in the text. This piece of quartz was used for all later experiments.

27. Compare the experiments of Elster and Geitel on the plane surfaces of liquid and solid alkali-metal layers in rarefied hydrogen (Berlin Sitzungsber. *6* 134 (1894); *11* 209 (1895)). The authors established the fact that the dependence of the effect on the direction of polarization is due to peculiarities in the absorption of light by the substance [Ann. Phys. *61* 445 (1897)].

28. To this simple case correspond the forces which Helmholtz assumes in his electromagnetic theory of dispersion (Wiss. Abh. *3* 503) with considerable success in explaining the phenomena of dispersion and absorption.

29. We note, in comparing columns 2 and 3, that the effect of the spark is somewhat less than that of the arc, especially at the lowest value of outside force. I formerly (4) thought that this was due to the electrostatic forces which the electrons, which are simultaneously in the space between U and E, exert on one another; for these forces are to be set proportional to the number of these electrons, i.e., the momentary intensity of the light, and would be greater for the spark than for the arc; furthermore they would be directed oppositely to the outside force. The difference between the effects of the two kinds of light is, however, adequately accounted for by the difference in the initial velocities produced by them (26, 31); while no electrostatic forces of the supposed kind showed themselves in any other way.

30. As in column 2 of Table 5.

31. The fact that this occurs even at UE = 5 mm. shows to what a great extent tangential components of velocity are present.

32. Similarly, the data obtained with retarding forces greater than 0.5 volt and without the sheath (Tables 8, 9) were regarded as unaffected.

33. See (23) for the notation.

34. These are relatively large in this case, for the galvanometer records only instantaneous values of the very variable intensity of the light. In the corresponding investigation on Al and Pt I went back to the electrometer which gives readings corresponding to average values of the intensity, and, when the deflections are small enough (13) makes the position of the "corner" very clear.

35. If two plates of different metals were placed opposite one another in a perfect vacuum, the "corner"—in experiments like the above one—would indicate the true "magnitude of the contact PD between the metals.

36. The values of U(—X) required for the correction were obtained by direct observation or by graphic interpolation on a sufficiently large-scale diagram.

37. The difference between the —1.20 volts obtained for the zero-point in these runs, and —1.1 volts in Table 10, is probably due to the fact that the former runs were made with the arc burning steadily for some time before the observations began, and the latter with the arc lighted only for the moment of the observation and emitting a hissing sound. The hissing arc seems to act in more nearly the same way as the metallic arc (cf. 26).

38. The zero of P.D. was shifted to the abscissa of the "corner" which was obtained by interpolation (Figs. 3, 32); the ordinates were then reduced to the scale used elsewhere, setting U = 0.645 when X = —0.030 volts.

39 The P.D. between the plates—E negative to U—seems to have been established during the first illumination of U; which suggests polarization of E perhaps by a layer of negative ions formed by absorption of cathode rays in the residual vapor (12). With carbon and Pt the P.D. was in the same sense, but not so large.

40. Note that our observations prove nothing against the possibility of inside velocities of a much smaller order of magnitude.

41. Neither law gives the observed distribution of outside velocities, and each requires that the smallest inside normal components should be the most numerous. Perhaps the latter are suppressed by the very strong absorption of the outer layers of the substance for slow electrons such as would come from the inner layers.—In an experiment of Hallwachs [Tagebl. der Heidelberger Natur f.—Vers. 214 (1890)] a transparent silver coating precipitated on quartz, when illuminated from the quartz side, gave off negative charge on the other side; this shows that all the layer of the substance which is reached by the light plays a part in the effect.

42. These numbers would presumably be increased if the surface were smooth; those just below them would be diminished.

43. Helmholtz "Erhaltung der Kraft" p. 47, 1847.

44. Lenard, Ann. Phys. *46* 584 (1892); mercury Table XVII there.

45. Hydrogen seemed less negative than air, at least towards water [Ann. Phys. *46* 627 (1892)] according to J. J. Thomson [Phil. Mag. *37* 341 (1895)], it would even be positive towards water.

46. Lenard, Ann. Phys., *51* 240 (1894).

47. J. S. Townsend finds [Phil. Mag. (6) *1* 198 (1901)], that material negative ions, like cathode rays, can produce new ions in gases; apparently there is no definite limiting speed for those.

48. This deflection was not actually observed; the capacity of the electrometer system had been raised from 1.14×10^{-10} farad to 501.1×10^{-10} farad; the observed deflection was 14.5. The potential of R was 120 volts negative to E.

49. Computed, as proportional to the pressure, from O. E. Meyer, Gastheorie, Table on p. 192.

50. 4.5 to 14×10^7 cm/sec. (cf. 23).

51. The free path of such particles would be $4\sqrt{2} = 5.7$ times as large as that of gas-molecules [cf. J. C. Maxwell, Phil. Mag. (4) *19* 29 (1860)].

52. 0.67×10^{10} cm/sec. [Ann. Phys. *64* 287 (1898)].

ELECTRICAL WORLD AND ENGINEER

A RESUMÉ OF INCANDESCENT ELECTRIC LAMP EXHAUSTING.

BY S. E. DOANE.

The exhausting of incandescent electric lamps has developed into a highly specialized branch of the lamp manufacture. In order to crowd a description of the development of this portion of the art into the limits of one article, it will be necessary to abbreviate portions of this description considerably. The history of the art up to the development and adoption of the present chemical exhausting method will be passed over rapidly. The latter method will be considered as thoroughly as the allotted space will permit.

The first incandescent lamp of the modern type ever constructed was exhausted on a mercury pump. Mercury pumps were used for lamp exhausting for nearly twenty years before they were superceded by the present chemical process. These mercury pumps were of two general types. Each type had its advantages and disadvantages, but overshadowing all was the need for better brains than could be obtained for the attendance demanded by all mercury pumps.

Either type of pump required active, intelligent men of strong physique. Men with these three qualities were fitted for far more pleasant duties, so that the supply of such men was always far short of the demand. The result was that the pump rooms always contained many men who, while possessing some of these qualities, were not completely qualified for the exacting service. Many of those who were qualified, and who, for brief seasons, filled the hearts of the lamp manufacturers with joy and hope for the future, would be found after the first pay day to be confirmed drunkards. Drinking men seemed more numerous in the pump rooms than elsewhere. I can see, as I look back, that this was because we tolerated more of it in the pump rooms than elsewhere. We were thus obliged to put up with insufficient mental capacity on the part of strong, faithful workmen, accepting the widened voltage range, shortened life and decreased candle-hour performance of the lamps improperly exhausted, year after year, gradually improving our condition as we developed the processes. The changes and improvements did not essentially modify the general practice, which was as follows:

The mercury pumps used by all lamp manufacturers in this country, which commenced operation not later than about 1885, were of the Sprengel type. Many of the companies began about this date to change to the Geissler form of pumps. Companies starting at a later date without exception so far as the writer can learn, used the Geissler form. The reasons for this will appear as we discuss the faults of the Sprengel pumps.

The Sprengel pump consisted essentially of a stream of mercury falling through a glass tube. All systems of this class had the following good qualities and faults:

The pumps gave a good vacuum, were cheap, simple to construct and to repair. When a pump failed only one lamp was injured. Every lamp was individually exhausted, which insured its being exhausted at just the proper voltage, when conditions were uniform, providing the operator was competent. We were content to have a pump which would procure for us a good vacuum, when the business was young. It was some time before we awoke to the fact that there were other requirements.

As we discovered the various new requirements, we also discovered fundamental faults with our apparatus and methods. These faults were finally found to be so serious that so far as I can learn every company in the country but one abandoned the Sprengel form of pumps for the Geissler form before ultimately adopting the chemical exhausting process.

At least every third man in the pump room (the men worked in teams of three in the best developed system) had to be an expert. The men were much exposed to the poisonous fumes of the mercury. Their hands were almost always black with an amalgam of mercury and grease. Many men were incapacitated because of mercury poisoning, and as this became known it became more difficult to secure the requisite grade of intelligence.

The men were required to be on their feet all day, working almost constantly with their hands on a level with their shoulders, a blazing row of lamps in front of them and sometimes behind them. While every effort was made in summer to keep the pump rooms cool, air drafts were tabooed and there was no way of escaping the light and radiant heat from the lamps. Add to this the danger to health and it will be seen how difficult it was to obtain the kind of men required.

Pumps did not all work at the same speed. The glass tubes from which the pumps were made were of different diameters, which was one reason for the differing speeds. The cleanliness as well as the diameter of the principal glass tube of the pump affected its speed. The diameter of the hole in the glass tube attached to the lamp through which the air was exhausted also affected the speed. The differing speeds was a matter of much importance for the following reasons:

The completed lamp must not only be free from gases and vapors, but must also have had those parts capable of giving off gases and vapors, thoroughly freed from them. The only way we knew to accomplish this was to highly heat everything we wished to free from gas. We had three things to heat: the glass, the filaments and the joints between filaments and leading-in wires.

The glass was heated by an asbestos cone-shaped hood painted black on the inside. The heat from the lighted lamp furnished all the heat necessary. The lamps could be heated hot enough to cause the bulb to collapse if the hoods were made too thick. The filaments were also heated sufficiently by the current, but the joints were not heated sufficiently unless the current was passed through the lamps at a time when the gases were of just the right pressure to allow current to pass across the vacuous space from joint to joint. The current would not pass across this space, if the gas pressure was either too low or too high, and we had very little latitude in this respect. If we put sufficient voltage on the lamps to pass this current from joint to joint before the gas pressure in the lamps was sufficiently high, we burned the surface of the filaments. Filaments thus burned varied in color from light bronze to sooty black. If we waited too long and the gas pressure had been a little too much reduced, we could only pass this current from joint to joint by putting a destructively high voltage on the lamp, and if it had been too much reduced we could not heat the joints at all.

We found difficulty in making uniform filaments, which difficulty we still have, in a much reduced degree. This non-uniformity made it necessary for us to burn each lamp on these pumps at a different voltage, as at the same voltage a lower voltage lamp would get hotter than a higher voltage lamp and a hotter lamp would exhaust more quickly than one relatively cooler. Thus it will be seen, lamps were exhausted at various speeds for the reasons that (1) the pumps themselves were of different speeds; (2) the tubes through which we exhausted the lamps were contracted to slightly different diameters, and (3) the lamps were only exhausted at the same temperatures when the judgment of the operator was good.

The Geissler pump enabled us to get around these difficulties, but also introduced some of its own. The advantages were as follows:

1. The pumps were all of the same speed. 2. While the lamps were not exhausted through tubes any more uniform, the "slow" lamps being connected to the same reservoir as the "fast" lamps they balanced up fairly well, as we had twenty or more lamps on one reservoir. 3. We could not exhaust the lamps at so nearly the same filament temperature, but the conditions under which we exhausted made all the lamps of the same tempera-

ture of glass, and consequently of the same temperature and pressure of gas. This was because all the lamps on one Geissler pump were heated in one hood. This hood was raised to a high temperature by gas flames. We did not depend upon the filaments to produce the initial temperature which very much reduced the liability to burn the filaments.

In addition to these three important advantages we could keep all hoods at the same temperature, start all pumps simultaneously, give all pumps the same number of strokes, flash all lamps simultaneously, thoroughly protect the mercury from contact with the air, and we required only one high-grade man in the pump room where formerly one-third of the operators had to be high-grade men.

We now felt that a great stride had been made in the exhaustion of incandescent lamps, but additional experience with the Geissler pump brought to light faults which still left much to be hoped for. The faults were as follows:

1. They were more expensive to operate, for the following reasons: (*a*) If one lamp leaked, the whole lot of lamps on this pump could not be exhausted. If the leak was only a small one, we would damage all the lamps on the pump. (*b*) The pumps were fragile, and if a lamp was accidentally broken, or if in any other way air was admitted accidentally, the pump was liable to be ruined. Lamps had to be more carefully inspected for leaks and glass work had to be more carefully done.

2. We still were unable to make lamps of exactly the same voltage. The lamps on one pump would necessarily have to be handled as a unit, which would mean that lamps designed for the same voltage would all have to be exhausted at the same voltage.

It became increasingly apparent as the effort was made to improve quality and reduce cost, that it would be strongly advisable if some means be found for individually exhausting lamps which did not possess the prohibitive faults of the Sprengel pump system. Some of the companies went so far as to construct some very small Geissler pumps to take one lamp each. It is hard to say what the outcome of this would have been, had not the chemical process been developed about this time.

The mechanical pump systems came into use about this time. All of them were open to the objections which held with the Geissler. Pump makers did not seem to appreciate the fact that whether a pump used mercury or not, it was simply and solely a pump. Some very good mechanical pumps were made, but most of them had a capacity greater than that of any Geissler pump. In order to get a reasonable output for the money invested, it was necessary to exhaust an even larger number of lamps simultaneously. This offered no escape from the troubles of the Geissler pump systems, and hence came into only limited use.

The chemical process was brought to us by a lamp maker. He knew the drawbacks of the mercury systems. This process possessed the advantages of the Sprengel system, the advantages of the Geissler pump system, and also some advantages of its own, without the conspicuous disadvantages of any of the previous systems.

While the Sprengel pump system only required that every third operator should be an expert, the chemical system required that every operator should be an expert, but it made it possible for us to secure experts, by entirely removing the disadvantages which made it so difficult for us to get a good class of operators. We found we had no difficulty nor do we now have any difficulty in securing plenty of young women of good intelligence who find the chemical exhausting work rather pleasant than otherwise. Every operator sits down to her work, has only one lamp on the pump at a time and is able to exhaust every lamp according to its individual requirements.

Two articles of any kind differ in some slight degree. This is true of incandescent lamps with special reference to the manner in which they exhaust. It may be that in one the joints between the filament and the platinum wires are larger or the joints are a little closer to the glass stem, or that the lamp has not been heated quite so hot in the preliminary heater or perhaps the bulb is of slightly different internal dimensions. Be the causes what they may, the differences are sufficiently marked to be quite apparent to the operators. This was all fully realized during the closing days of the mercury pump systems, but the vital difference this made to the candle-hour performance of the lamps has never been so fully appreciated as since we began to use the chemical process of exhausting. The chemical process of exhausting consists roughly of mechanically exhausting a heated lamp to a pressure represented by a column of mercury about .125 mm. high. This is equivalent to about 1/6000 of an atmosphere. The lamp is sealed off from the pump and phosphorous is vaporized and passes into the lamp bulb while the filament is very hot and while an electric current is passing through the gaseous contents of the bulb. The vapors of this metal enter into an electrochemical combination with the gases, forming solid precipitates, if the conditions are proper.

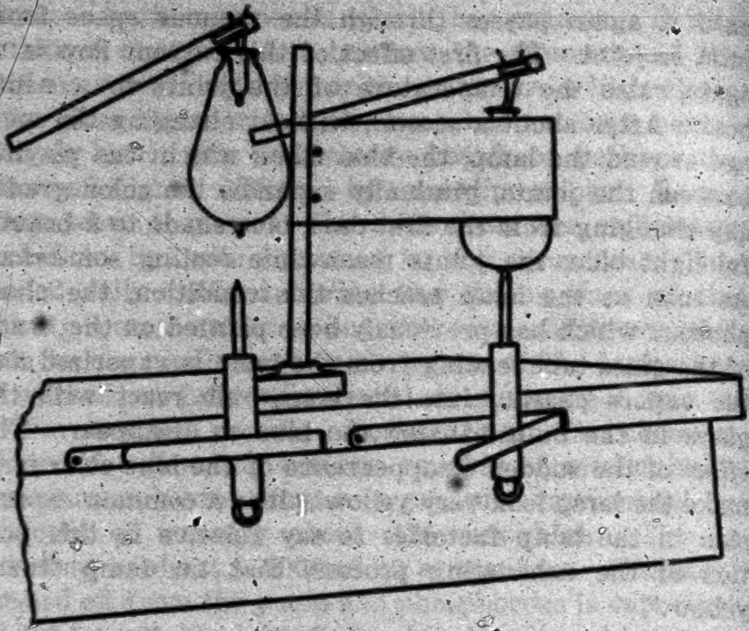
This whole operation from the time the lamp is first lighted up on the pump to the time it is completely exhausted requires approximately sixty seconds. During this time the following changes take place in the lamp bulb:

About one-half minute after the lamp is first placed upon the pump and before the lamp is shut off from the pump, current is passed through the filament. Current also passes from joint to joint across the vacuous space, heating both joints white hot. The joints are held at this temperature for a few seconds after which the current is reduced and the pump is given a few seconds to remove the gases which are dislodged by this heating. This takes about five seconds under usual conditions. The tube connecting the lamp to the pump is then closed very close to the lamp. The current is again increased until it again passes through the vacuous space from joint to joint. The first effect of this current flow is to again raise the temperature of the joints to a white heat. After about a second, without changing the voltage around the lamp, the blue flame which was playing between the joints, gradually expands, the color gradually changing from the first dark blue shade to a beautiful light blue, the joints meanwhile cooling somewhat. As soon as the lamp reaches this condition, the phosphorous which has previously been painted on the inside of the glass tube leading from the lamp is vaporized and the vapors passing into the lamp bulb react with the gases in the bulb, causing the blue to disappear. The effect of the sudden disappearance of the blue color is to make the lamp look very yellow. It is a common expression in the lamp factories to say relative to this portion of the exhausting process, that the lamp "turns yellow."

In order that the current may pass from joint to joint across the vacuous space the pump must necessarily produce a higher vacuum than is usual with mechanical pumps. The pump used in this work is of the ingenious variety which depends upon an oil-covered piston to displace all the air in the pump cylinder. The pump is so constructed that a little oil is always passing into the cylinder and is forced up through the exhaust valve with the gases which are being expelled. This oil is used over and over again. It is free from occluded gases, contains no volatile oils, and has a low surface tension. Care is taken to select an oil with these characteristics.

A mechanical pump of this description never produces a vacuum so high that there is any difficulty in passing current from joint to joint in the lamp being exhausted upon it. Care has to be taken with these pumps to be certain that they are always in such condition that they will produce a sufficient vacuum.

The present exhausting system has its faults. Any exhausting system will have faults, until a system is devised which automatically keeps itself in repair and



CHEMICAL EXHAUSTION OF LAMPS.

also automatically and perfectly exhausts lamps without the interposition of human judgment. The faults which concern us the most are as follows:

1. We must still have expert operators. 2. We still depend upon a system of pipes and valves which will occasionally develop leaks. 3. Pumps occasionally get out of order. 4. The chemical reactions which produce the vacuum are sensitive and atmospheric and chemical conditions occasionally give us new problems.

A better understanding of how this chemical exhausting is performed will be gained from the following description referring to the accompanying sketch. The operators are all seated in front of a long bench behind which are a number of little pumps. These pumps occupy about four feet of floor space and stand less than three feet high. They run continuously, being piped by the shortest possible connections to the face of the bench. Each operator utilizes one cylinder each of one of these pumps.

In the sketch the lamp on the left is exhausted and ready to be removed from its clip. The lamp on the right is shown thrust into a bit of rubber tubing. This tubing passes through a pinch cock on the edge of the bench.

In front of the lamp is a piece of metal that shields the eyes of the operator when the lamp is brightly lighted. The piece of metal can be swung around so that it can shield the operator from the light from either lamp.

While the lamp on the right is being exhausted, the lamp on the left is being removed from the clip which suspends it by the leading-in wires, another lamp is then thrust into the rubber tubing and connected to the clip. By this time the lamp on the right is sufficiently exhausted and current is passed through it by means of a rheostat on the left of the operator, and the process of exhausting is completed as indicated earlier in this article. After the exhausting is completed the tube through which the air is exhausted is sealed off by the blow pipe flame which much resembles the jeweler's blow pipe flame, familiar to every student.

Bits of glass, dust, moisture from the air, phosphorous, etc., collect in the pipes and interfere at times with the action of the pinch cock valve. It is necessary to watch very closely to see that the lamps are being exhausted under the desired conditions.

Each type of lamp behaves a little differently from another type.

The tubular lamp is difficult to exhaust because the phosphorous gases are heavy, the residual gases in the lamp are light; the phosphorous is in the form of gas at a high temperature only, and the lamps cool quickly from the high temperature of the heater in which it was heated before being placed upon the pump.

The space in this lamp is narrow and long and as the glass of the lamp is always somewhat cooler than the phosphorous vapors, this added to the other difficulties mentioned makes it necessary that the tubular lamps be handled by our most skilled operators.

Lamps with small bulbs are difficult to exhaust for the last-named reason and also because they are so small that it is difficult to avoid vaporizing too much phosphorous. If too much phosphorous is vaporized the bulb of the lamp is discolored. Each size of lamp and each shape of bulb behaves a little differently from any other size or shape of bulb. The two examples are given above as illustrations only.

As the tube, through which the lamp is exhausted, which also carries the phosphorous must necessarily be of a reasonable thickness, in order not to collapse when the blow pipe flame is applied to vaporize the phosphorous, it also must possess considerable heat capacity. As often only a very small amount of phosphorous vapor is required for the reaction there is every opportunity for an unskilled operator to use too much phosphorous, thereby making a lamp unsalable. An operator on a small lamp, or on a tubular lamp, or on a lamp in which the reaction is progressing freely, must be especially careful to withdraw the flame from the phosphorous-carrying tube long before the reaction is completed, as the phosphorous will continue to vaporize until the tube has cooled considerably. If an operator is sufficiently skilled, she can tell by watching the progress of the reaction in the lamp bulb as indicated by the changing color and form of the blue light which fills the bulb, when the reaction is about to be completed. A skilled operator will exhaust lamps with almost no rejections from one day to another. Such an operator is always very fast and always produces lamps of high quality. The contrary is true of one who is not skilled.

One reason that an operator who can always quickly vaporize just enough phosphorous and who does not vaporize too much phosphorous produces high-quality lamps is that the voltage at which it is necessary to operate these lamps in order to produce the temperature and the cross currents is such that if a lamp were burned at this temperature for many seconds the lamps would have passed much of its useful life. It is obvious that every second that can be saved when the lamp is being burned at this temperature adds hours to the life which the prospective customer will obtain from this lamp. This assurance that all the lamps exhausted by an expert operator will give practically the same life and candle-hours, other conditions being equal, is of great value.

Under the mercury pump régime the lamps burned not less than twenty minutes each at a voltage not less than 10 per cent. above normal. During only the last few minutes would the vacuum approximate that at which the lamps would ultimately burn. The lamps on the mercury pumps were also burned in addition to this at a voltage at least as high as that ever reached by the chemical methods and for a longer time.

Burning lamps at high incandescence before the vacuum becomes sufficiently good discolors the filaments. This raises the voltage at which the lamps deliver the candle-power for which they are designed, providing a good vacuum is ultimately produced in these lamps. When such lamps are shipped to the customer they are labeled to be operated at higher voltages than would have been the case had the lamps been exhausted by the modern process. In the days of the mercury pumps one of the principal causes for rejection of the lamps from some of the pump room operators was the blackened filaments resulting from this cause. In rejecting lamps for this cause, lamps with filaments only slightly burned were necessarily passed for shipment.

Such lamps would rise rapidly in candles at the beginning of their life and fall almost as rapidly after the first 50 or 100 hours. This condition has been almost entirely eliminated. Much of the improvement in lamp quality in recent years can be traced directly to better methods of exhaustion.

Lamps in which the gases have not been thoroughly eliminated from the joints between the filaments and the platinum wires will fall rapidly in candles when put into service. Much of the rapid decline in candles in the lamps exhausted on mercury pumps was due to the joints between the filament and the platinum discharging gases while in service.

The closer specifications to which modern lamps can be shipped can also be partly traced to this improvement in exhausting as indicated in the preceding paragraphs. When the history of the development of the incandescent lamp is written the most interesting chapters will be those which deal with this portion of the story. Only a very brief outline of the subject has been given above. Many hundreds of experiments and life tests and the expenditure of a great deal of money is summed up in this brief description.

MAX VON RECKLINGHAUSEN, OF NEW YORK, N. Y., ASSIGNOR TO COOPER HEWITT ELECTRIC COMPANY, OF NEW YORK, N. Y., A CORPORATION OF NEW YORK.

MEANS FOR EXHAUSTING INCLOSED RECEIVERS.

946,008. Specification of Letters Patent. Patented Jan. 11, 1910.

Application filed July 30, 1904. Serial No. 218,021.

To all whom it may concern:

Be it known that I, MAX VON RECKLINGHAUSEN, a subject of the Emperor of Germany, and resident of New York, county of New York, State of New York, have invented certain new and useful Improvements in Means for Exhausting Inclosed Receivers, of which the following is a specification.

It has been found advantageous in exhausting containers of mercury vapor apparatus, whether designed for use as lamps or as vapor converters, to make use of magnesium for absorbing some of the gases which remain after a certain degree of exhaustion by pumping has been attained. A difficulty with the employment of magnesium for this purpose resides, however, in the fact that whereas the containing vessels for most of the mercury vapor apparatus are of glass, yet the magnesium in its active state attacks glass and, therefore, is less adapted for use in assisting the exhaustion than it would otherwise be. There are, however, ways in which the magnesium, particularly when made active through the action of heat, can be prevented from attacking the glass, and, of course, the injurious effects of the magnesium for the purpose indicated can be avoided, and excellent results obtained, by using a container which is not made of glass but of some metal such as iron.

My invention contemplates the use of magnesium or other metal for absorbing air or other purposes and the safeguarding of the same from the chances of doing injury, either by so mounting the magnesium or other metal in a glass container as to prevent its coming in contact when in a heated state with the material of the container, or by constructing the container wholly of some metal such as iron or some composition of metals not attackable by the heated magnesium or other metal.

In the drawings Figure 1 shows a mercury vapor converter in elevation; and Fig. 2 shows a section of a portion of the mercury vapor apparatus illustrating in perspective certain details of the apparatus common to the structure of Fig. 1 and Fig. 2.

In the drawing, Fig. 1 shows a mercury vapor converter comprising a container, 1, positive electrodes, 2 and 3, and a negative electrode, 4, of mercury. For convenience I will specify magnesium as the metal to be employed for absorbing air.

Inside the container 1 I mount, somewhat in the manner indicated, a plate or support, 5, of magnesia having a depression, 6, at its top in which a portion, 7, of magnesium is placed. With the terminals of the strip 7, I connect metallic wires or brackets 8, 9, provided with portions 10, 10, which extend under the plate 5 and support it in position. The brackets 8 and 9 are connected with the lead-wires, 11, 11, which pass through the walls of the container 1 and are connected with the circuit wires leading to an electric generator, 13.

When used for the purpose indicated above, the apparatus is exhausted in the usual way. When, however, the exhaustion has been carried to a sufficiently high degree, the container may be sealed off and the generator 13 started into operation. Thereupon the strip 7 of magnesium will be heated or melted and in that state it will absorb the injurious nitrogen and oxygen remaining in the container, thus completing the exhaustion of the apparatus.

When it is desired to employ magnesium in order to secure a very high degree of exhaustion and without any danger of injury to the container, the latter may be made entirely of some metal or association of metals such as will not be attacked by magnesium in its active state. A metal suited for the purpose is iron.

I claim as my invention:—

1. The combination with a closed container, of a holder within the container, magnesium within the holder, and a source of electric current connected with the opposite ends of the magnesium whereby the same may be rendered active for absorbing injurious gases in the container.

2. The combination with a closed container, of an insulating holder inside the container, magnesium in the holder, and a source of electric current connected with the magnesium at points of different potential.

3. The combination with a closed container, of an insulating vessel inside the container adapted to hold a conducting liquid and a material in said vessel adapted to remove gases from the container, together with means for heating and melting said material.

Signed at New York, in the county of New York, and State of New York, this 22nd day of July A. D. 1904.

MAX VON RECKLINGHAUSEN.

MATTHEW M. MERRITT, OF MIDDLETON, MASSACHUSETTS, ASSIGNOR TO BOSTON INCANDESCENT LAMP COMPANY, OF DANVERS, MASSACHUSETTS, A CORPORATION OF MASSACHUSETTS.

PROCESS FOR EXHAUSTING LAMPS.

No. 909,211. Specification of Letters Patent. Patented Jan. 12, 1909.

Application filed January 27, 1908. Serial No. [illegible].

To all whom it may concern:

Be it known that I, MATTHEW M. MERRITT, a citizen of the United States, residing at Middleton, in the county of Essex and State of Massachusetts, have invented an Improvement in Processes for Exhausting Lamps, of which the following description, in connection with the accompanying drawings, is a specification, like letters on the drawings representing like parts.

My invention relates to the manufacture of incandescent lamps, and consists more particularly in a new process of employing a chemical assistant in the exhaustion of the bulb.

The process of lamp exhaustion, as heretofore carried out, has consisted generally in exhausting the bulb to some selected point by means of a vacuum pump. The pump is then cut off from the bulb and the filament brought to a state of high incandescence by the passage of an abnormal current therethrough to expel the gases absorbed in the filament and the joints thereof and at the same time suitable chemical substances are permitted to act upon the deleterious gases, and particularly the oxygen, remaining within the bulb. The object of this is the conversion into harmless compounds of those gases which remain after mechanical exhaustion in the highly rarified atmosphere of the bulb and would be injurious to the life or efficiency of the filament. This process of chemical exhaustion has been well-known in the art for many years. More recently, this process has been practiced by inserting the chemical agent in the open ended tubulature which it is customary to secure to the tip of the bulb about to be exhausted. This tubulature having been connected with the pump and exhaustion carried to the required degree, which is naturally short of the final vacuum, communication is interrupted between the pump and the tubulature below the chemical. The lamp filament is then brought to intensive incandescence and simultaneously the chemical in the tubulature (if, as usual, a volatile chemical is employed) is heated to cause it to unite with the occluded gases of the bulb and the deleterious gases driven from the carbon of the filament and the joints. As soon as chemical union has taken place, which is determined by the visual disappearance of an intensely blue or violet colored glow within the bulb, the latter is sealed off from the tubulature above the chemical, the lamp then being in a practically finished state.

The process of introducing a chemical agent into the tubulature has material defects. The procedure involves starting the chemical action by a violent heating of the tubulature before the sealing off of the bulb. It is difficult even for an experienced operator satisfactorily to volatilize the chemical in the tubulature without occasionally so overheating the walls thereof, and particularly at its slender neck where it is joined to the bulb, as to form a slight crack or fissure with the consequent admission of air. It has been found that if even a slight amount of air is admitted before the chemical action is completed, the vacuum is not only destroyed or impaired, but the chemical action is accompanied by the production of a brownish yellow deposit on the interior of the bulb which makes the lamp defective and unsalable. It is a frequent occurrence in carrying out the process described, to overheat the tubulature while volatilizing the chemical and permanently discolor the bulb. This procedure also involves the somewhat hurried sealing off of the bulb from the tubulature while the chemical action is at its height. This hasty sealing of the bulb is often accompanied by the formation of a slight crack at the seal, or the admission of a small amount of air before the seal is perfected, which results as above in spoiling the lamp and in impairing or destroying the vacuum. After completion of mechanical exhaustion and before the chemical action takes place, much of the remnant gaseous matter is in the form of moisture. This becomes apparent to the eye in the form of an illuminated fog-like haze before the filament is brought to intensive incandescence, which haze hovers about the narrow opening between the tubulature and the bulb. Under the process referred to, it is extremely difficult to properly extract this moisture. For some reason, it tends to seal the narrow opening of the tubulature and prevent the entrance of the volatilized chemical into the bulb, while at the same time the volatilized chemical tends to prevent the moisture from leaving the bulb. Even if the pump is kept in communication with the bulb during a preliminary heating of the chemical and filament, the pump tends to suck the chemical out of the tubulature while extracting the moisture in the bulb only with the greatest difficulty. This trouble is also enhanced by the fact that the tubulature through which or into which the moisture should pass, is raised to a high heat tending to drive back the moisture into the bulb. The final sealing of the lamp which is performed after interrupting communication with the pump also tends to drive any attracted or absorbed moisture in the tubulature out of it and into the rapidly cooling and relatively cooler bulb.

Prior to the exhaustion process the bulb is customarily heated in an oven to drive off the absorbed moisture and gases. Unless the exhaustion is effected rapidly, however, the subsequent cooling of the bulb causes a material re-absorption of those gases. Again, if the filament is raised to intensive incandescence without the presence of the volatilized chemical the expelled gases tend to unite with the hot filament greatly to its detriment. It is difficult to perform the present process rapidly enough to prevent a material cooling of the bulb, and, owing to the remoteness of the chemical from the filament and the check which the expelled moisture puts upon the entrance of the chemical into the bulb when the filament is raised to intensive incandescence, a large portion of the expelled gases undoubtedly combine with the highly heated filament, burning and blackening the same.

My process provides an entirely novel and different mode of performing the exhaustion of the lamp, whereby it can be completed with fewer steps and in less time than with the present process, being at the same time free from the defects above pointed out.

My process will be best understood by reference to the following description, wherein, for illustrative purposes, there is given in detail the preferred mode of performing it, while its scope will be more particularly pointed out in the appended claims.

The drawing shows diagrammatically a lamp bulb *a* with its contained filament *b* and the attached tubulature *c*, all of which are typical of a lamp of the usual construction. The end of the tubulature is shown inserted in a rubber socket connection *d*, which is in communication with an air pump (not shown). The latter may be of any description capable of exhausting to the degree required as a preliminary for the chemical action.

Preferably within the normal bulb space, instead of in the tubulature as before, and preferably, although not necessarily, upon the inner walls of the bulb itself, as at *e*, there is deposited a small and preferably definite amount of some one of the well-known agents suitable for chemical exhaustion, such, for example, as red amorphous phosphorus. The location of the chemical shown in the drawing, is particularly advantageous, for it is in immediate proximity to the porous pasted joints of the filament wherein are absorbed the major portion of the deleterious gases finally expelled. The insertion of this chemical (which in the drawing is shown greatly exaggerated in amount) is affected at some prior stage in the process of the lamp manufacture and may be conveniently accomplished before the tubulature is joined to the bulb. The lamp having been previously warmed or heated, as in an oven, to drive out as large a portion as possible of the absorbed gases, its tubulature is connected with the pump, as shown in the drawing, and there remains for a few moments until mechanical exhaustion to the required degree has been accomplished. Meanwhile the filament may be made to glow slightly by the passage therethrough of a current of normal or somewhat less than normal strength. This point having been reached, I then preferably bring the filament to intensive incandescence and at the same time heat the glass bulb, and particularly at the point *e* where lies a deposit of chemical, the connection with the pump, however, preferably remaining uninterrupted. This volatilizes a portion of the chemical already within the bulb, causing it to act, not only upon the residual gases of the bulb space, but also upon the expelled gases from the filament and the joints thereof and the gases driven out from the pores of the bulb, these gases, however, being freed in the immediate presence of the volatilized chemical and having no opportunity to unite chemically with the filament. The heat applied to the bulb to volatilize the chemical also materially assists in expelling the absorbed gases. During this operation the pump easily withdraws the moisture discharged from the filament and the bulb through the free open passage of the tubulature which is obstructed by neither volatilized nor unvolatilized chemical. As soon as the moisture has been withdrawn and before the chemical has been completely volatilized, the lamp is sealed between the bulb and the tubulature at *f*, such sealing hermetically closing both the bulb and the tubulature, which latter remains in the socket. The chemical remaining within the bulb, which latter is now in its complete, hermetically-sealed state, is then again heated to complete its volatilization and the filament simultaneously brought to intensive incandescence. This operation will be accompanied first by the appearance and then the disappearance of the blue glow referred to, which will indicate the completion of the exhaustion of the lamp. The severed and sealed tubulature may remain in its socket until a fresh lamp is to be exhausted, when it may be replaced by the tubulature attached thereto. It will be seen that the final step of this process of exhaustion, as here performed, is the chemical action upon the atmosphere of the bulb after the latter is hermetically sealed in its completed state and after every step which can in any way affect the vacuum therein has been performed. This absolutely avoids the possibility of any air or gases entering into the bulb during the final chemical action. It also permits this final chemical exhaustion to be carried on carefully and, if desired, leisurely. In fact, any desired interval may elapse between the time of sealing of the bulb and the time of volatilizing the remaining chemical in the presence of the incandescent filament.

The present process requires the placing of an amount of chemical in the tubulature largely in excess of what is required for the actual chemical action which takes place. This is not only detrimental because the chemical absorbs and retains a considerable quantity of moisture, but more particularly because it is difficult or impossible for the operator to volatilize just the precise amount needed for the required chemical reaction. This required amount is a definite quantity and if exceeded will result in a discoloration of the bulb similar to that produced when air is admitted in excess through an accidental crack or fissure, as above described. The use of an excess amount of chemical, however, is a necessary consequence of its volatilization in the tubulature, for it is volatilized at a point comparatively remote from where it is needed and an indeterminate portion of it undoubtedly fails to enter the bulb at all. By my process, the amount of chemical can be reduced to substantially that which is required for the chemical action, this being a definite proportion which can be easily determined in each case. When this is volatilized it may be known that the action is complete and it is impossible for the operator to discolor the bulb by the volatilization of an excess amount of chemical as is the case in the present process.

It is to be observed that in my process the restricted entrance to the tubulature and the tubulature itself may be maintained in free communication with the pump up to the moment of sealing the bulb, so that all moisture and gaseous matter which it is possible for the pump to withdraw will be withdrawn without interference or opposition on the part of the volatilized chemical.

The manipulation in my process is so simplified that it can be performed with greater rapidity, and with less opportunity for the cooling of the bulb. As has been observed, however, the latter is no serious defect in my process for the heating of the chemical is accompanied by a heating of the bulb and the expulsion of the contained gases in the immediate presence of the chemical.

Other advantages, many of which will be apparent to those skilled in the art, follow from the use of my process but these, as well as the many modifications thereof and the many variations in the detailed steps thereof are unnecessary to mention; it being understood that my invention is not limited to the details here described but only to the broad principles claimed.

Claims:

1. The process of exhausting lamp bulbs which consists in inserting a volatile chemical agent within the bulb, placing the latter in communication with a pump, exhausting to the required degree, raising the filament to a state of incandescence and partially volatilizing the said chemical while said bulb is still in communication with the pump, sealing off the bulb and thereafter completing the volatilization of the chemical in the presence of the incandescent filament.

2. The process of exhausting a lamp bulb which consists in placing the latter in communication with a pump, exhausting to the required degree, raising the filament to a state of incandescence, acting upon the residual gases by a volatilized chemical agent while the bulb is still in communication with the pump, sealing off the bulb and thereafter acting upon the residual gases by a volatilized chemical agent in the presence of the incandescent filament.

In testimony whereof I have signed my name to this specification in the presence of two subscribing witnesses.

CONVERSION OF ELECTRIC OSCILLATIONS INTO CONTINUOUS CURRENTS BY MEANS OF A VACUUM VALVE.

by

J. A. FLEMING

PP. 476-487.

"On the Conversion of Electric Oscillations into Continuous Currents by means of a Vacuum Valve." By J. A. Fleming, M.A., D.Sc., F.R.S., Professor of Electrical Engineering in University College, London. Received January 24,—Read February 9, 1905.

An electric oscillation being an alternating current of very high frequency, cannot directly affect an ordinary movable coil or movable needle galvanometer.

Appliances generally used for detecting electric waves or electric oscillations are, therefore, in fact, alternating current instruments, and must depend for their action upon some property which is independent of the direction of the current, such as the heating effect or magnetizing force. The coherer used in Hertzian wave research is not metrical, since the action is merely catastrophic or accidental, and bears no very definite relation to the energy of the oscillation which starts it. Even the demagnetising action of electric oscillations, though more definite in operation than the contact action at loose joints, is far from being all that is required for quantitative research. It is obvious it would be an advantage if we could utilise the direct current mirror galvanometer for the detection and measurement of feeble electric oscillations. This can be done if we can discover a medium with perfect unilateral conductivity.

Some time ago, I considered the use of the aluminium-carbon electrolytic cell with this object. It is well known that a cell containing a plate of aluminium and carbon, immersed in some electrolyte which yields oxygen, such as dilute sulphuric acid or an aqueous solution of any caustic alkali, or salt yielding oxygen, has a unilateral conductivity within limits. An electric current under a certain electromotive force can pass through the cell from the carbon to the aluminium, but not in the reverse direction.

This action has been much studied and is the basis of many technical devices, such as the Nodon electric valve.

The electrochemical action by which this unilateral conductivity is produced involves, however, a time element, and after much experimenting I found that it did not operate with high frequency currents. My thoughts then turned to an old observation made by me in 1889, communicated to the Royal Society, amongst other facts, in a Paper in 1889, and also exhibited experimentally at the Royal Institution in 1890.[*] This was the discovery: that if a carbon filament electric glow lamp contains a pair of carbon filaments or a single filament and a metallic plate sealed into the bulb, the vacuous space between possesses a unilateral conductivity of a particular kind when the carbon filament, or one of the two filaments, is made incandescent. I have quite lately returned to this matter, and have found that this unilateral conductivity exists even with alternating currents of high frequency and is independent of the frequency. Hence, in a suitable form, it seemed possible that such a device would provide us with a means of rectifying electric oscillations and making them measurable on an ordinary galvanometer. The following experiments were, therefore, tried:—

[*] See 'Roy. Soc. Proc.,' vol. 47, p. 122, 1890, "On Electric Discharge between Electrodes at different Temperatures in Air and High Vacua," by J. A. Fleming, communicated December 16, 1889; see also 'Proceedings of the Royal Institution,'

Into a glass bulb, made like an incandescent lamp, are sealed in the ordinary way two carbon filaments, or there may be many filaments. On the other hand, one carbon filament may be used and a platinum wire may be sealed into the bulb terminating in a plate or cylinder of platinum, aluminium or other metal surrounding the filament. It is preferable to use a metal plate carried on a platinum wire sealed into the glass bulb, the plate being bent into a cylinder which surrounds both the legs of the carbon loop. The diagrams in fig. 1 show various forms of the arrangement. Diagram *a* shows a bulb with a single carbon filament surrounded by a metal cylinder, *b* shows one with two carbon filaments, and *c* a carbon filament and two insulated metal plates. The ends of the carbon filament which is rendered incandescent are marked + and − and the terminal of the other electrode of the valve is marked *t*. The bulb must be highly exhausted to about the pressure usual in the case of carbon filament incandescent lamps, and the metal cylinder or plate must be freed from occluded air.

Suppose that we employ such a bulb containing one carbon filament surrounded by a metal cylinder (see *a*, fig. 1). The filament may be of any voltage, but I find it most convenient to employ filaments of such a length and section that they are brought to bright incandescence by an E.M.F. of 12 volts. The voltage and section of the filament should be so arranged that the temperature of the filament corresponds with an "efficiency," as a lamp-maker would say, of 2·75 or 3 watts per candle. The filament is conveniently brought to incandescence by a small insulated battery of secondary cells. A circuit is then completed through the vacuous space in the bulb between the cylinder and the filament by another wire which joins the external terminal *t* of the metal cylinder and that terminal of the carbon filament which is in connection with the negative pole of the heating battery. In this last circuit is placed a sensitive mirror galvanometer of the movable needle or movable coil type, and also a coil which may

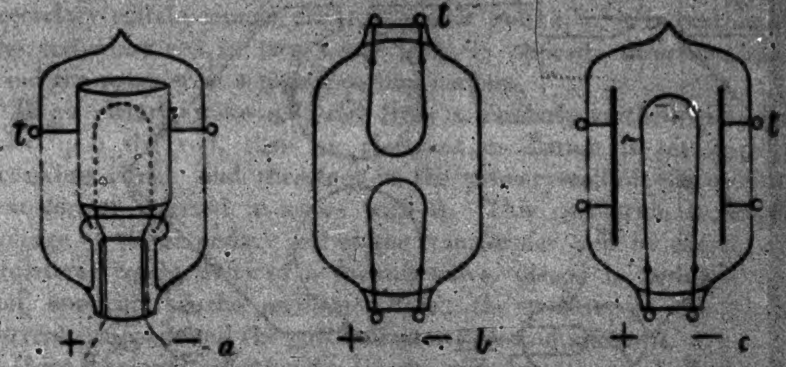
---

vol. 13, Part LXXXIV, p. 45, Friday evening discourse on February 14, 1890, "Problems on the Physics of an Electric Lamp," when this unilateral conductivity was experimentally shown.

be the secondary circuit of an air core transformer in which electric oscillations are set up. As is now well known, the vacuous space in the bulb permits negative electricity to move in it from the hot filament or cathode through the vacuous space to the cylinder or anode and back through the galvanometer and coil, but not in the reverse direction, as long as the cylinder is cool and the carbon filament not at a temperature much above the melting point of platinum. To illustrate the action of the bulb as an electrical valve, the following experiments can be shown:—

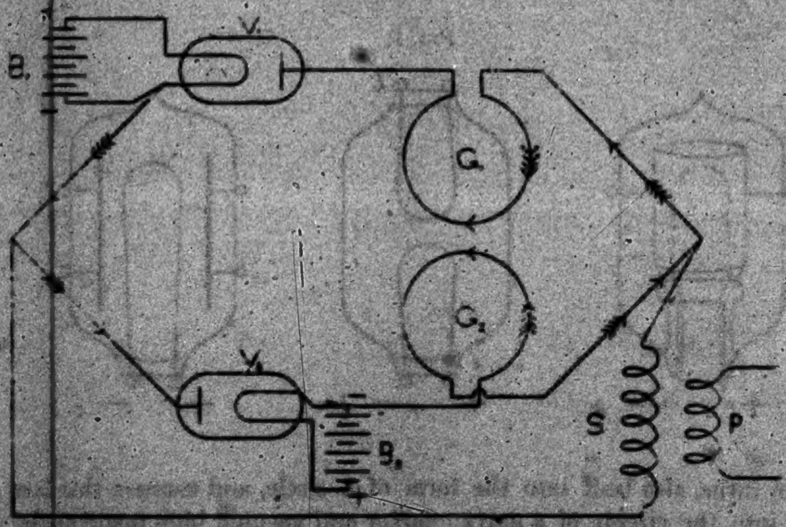
Electric oscillations are set up in a metal wire circuit by the discharge of a Leyden jar, as usual. This circuit takes the form of a thick wire of one or more turns, bent into the form of a circle or square. Some distance from this, we place another wire, of several, say eight or ten turns, also bent into the form of a circle, and connect this last wire into the circuit of a galvanometer and vacuum bulb made as described, so that it is a circuit having unilateral conductivity. On exciting the oscillations in the primary circuit by an induction coil we have an alternating high frequency magnetic field produced, which affects the secondary circuit at a distance. The oscillations in this last are, however, able to flow only in one direction. Hence, the galvanometer is acted upon by a series of intermittent but unidirectional electromotive forces, and its needle or coil deflects. Since the field is a high frequency field, we can show the screening effect of a sheet of tin foil or silver paper in a very simple and effective manner by the effect it produces in cutting down the galvanometer deflection when the metal sheet is interposed between the primary secondary circuits. Also, if we move the secondary coil away from the primary coil or turn the two coils with their planes at right angles to one another, then the galvanometer deflection diminishes or falls to zero because the induction is decreased. Accordingly, we have in this vacuum valve and

Fig. 1.



associated mirror galvanometer a means of detecting feeble alternating electric currents or oscillations. Another method is to employ a differential galvanometer and two vacuum valves. These must then be arranged, as shown in fig. 2, one circuit G_1 of the differential galvanometer is in series with one valve V_1 and the other circuit G_2 with the other valve V_2, but so joined up that currents flowing through the valves in opposite directions pass round the two galvanometer wires in the same direction as regards the needle and, therefore, their effects are added together on the galvanometer needle. Each valve must then have its own separate insulated battery to ignite the filament. Also, it is necessary that the connection with the oscillatory circuit must be made in both cases to the hot filament by that terminal which is in connection with the negative pole of the local battery used to ignite the filament (see fig. 2).

Fig. 2.



This arrangement of a differential galvanometer and two valves transforms, of course, more of the alternating oscillation into direct current than when one valve alone is used. It provides us with a means of detecting electrical oscillations not merely in closed circuits but in open electrical circuits.

When so using it, it is necessary to associate with the oscillation valve and galvanometer an oscillation transformer for raising the voltage. The resistance of these valves, when in operation, may be anything from a few hundred ohms up to some megohms, depending on the state of incandescence of the filament and upon the electromotive force employed to drive the current through the vacuous space, as well as upon the size of the filament and the plate.[1] This resistance does not obey Ohm's law, but the current increases to a maximum and then slightly decreases as the voltage progressively increases. The form of oscillation transformer employed with the device is as follows: A small air-core induction coil has a primary circuit, which consists of 52 turns of gutta-percha covered wire, wound in a helical groove cut on an ebonite rod 0·5 inch in diameter and 6 inches in length. The primary circuit is made of a No. 20 or No. 22 S.W.G. copper wire. The secondary circuit consists of 36,000 turns of fine silk-covered wire, No. 36, wound in six coils, each having about 6000 turns, and all joined in series. This secondary circuit has one terminal connected to one common terminal of the galvanometer and the other to the common terminal of the two oscillation valves (see fig. 4). The primary coil of this oscillation transformer has one terminal connected to earth and the other to a long insulated rod which acts as an aerial or electric wave collector. To prevent the direct action of the transmitter upon the secondary coil by simple electromagnetic induction, it is best to wind the secondary coil in two equal parts in opposite directions and to wind the primary in a corresponding manner.

If an electric wave sent out from a similarly earthed transmitter falls upon the rod, then an electrical oscillation is set up in the receiving circuit and therefore in the primary coil of the oscillation transformer inserted in series with it. This oscillation is raised in voltage by the secondary coil of the transformer, and by reason of the unilateral conductivity of a vacuum valve, placed in series with the coil, one part of the oscillation, viz., the positive or the negative current, passes round the galvanometer coils and affects it.

If we employ a sensitive dead-beat galvanometer of the type called by cable engineers a "Speaking Galvanometer," then intelligible signals can be sent by making small and larger deflections of the galvanometer corresponding to the dot and dash of the Morse alphabet; anyone who can "read mirror" can read off the signals as quickly as they can be sent on an ordinary short submarine cable with this arrangement.

The arrangement, although not as sensitive as a coherer or magnetic detector, is much more simple to use. Also it has one great advantage, viz., that it enables us to examine the behaviour of any particular form of oscillation producer. By means of it we can detect changes in the wave-making power or uniformity of operation of the transmitting arrangement, by the variation of the deflection of the galvanometer. Thus, for instance, if a spark-ball transmitter is being employed and the deflection of the galvanometer in association with the receiving aerial is steady, if we put the slightest touch of oil upon the spark-balls of the transmitter, their wave-making power is increased and the deflection of the galvanometer at once increases. Since the current through the galvanometer is the result of the groups of oscillations which are created in the receiving circuit, and since in the ordinary transmitter these oscillation groups are separated by wide intervals of silence, it is obvious that we can increase the sensitiveness of the above described arrangement by employing a very rapid break or interruptor with the induction coil. If, for instance, we employ a Wehnelt break with the induction coil or a high speed mercury break or alternating current transformer, we get a far better result as indicated by the deflection of the galvanometer than when employing the ordinary low frequency spring or hammer break.

The point of scientific interest in connection with the device, however, is the question how far such unilateral conductivity as is possessed by the vacuous space is complete. The electrical properties of these vacuum valves have accordingly been studied.

A bulb containing a 12-volt carbon filament rendered brightly incandescent by a current of about 2·7 to 3·7 ampères was employed. The filament was surrounded by an aluminium cylinder. The length of the carbon filament was 4·5 cm., its diameter 0·5 mm., and surface 70 square mm.

The aluminium cylinder had a diameter of 2 cms., a height of 2 cms., and a surface of 12·5 square cms. The filament was shaped like a horse-shoe, the distance between the legs being 5 mm. This filament was rendered incandescent to various degrees by applying to its terminals 8, 9, 10, and 11 volts respectively. Another insulated battery of secondary cells was employed to send a current through the vacuous space from the cylinder to the filament, connection being made with the negative terminal of the latter. The current through the vacuous space and the potential difference of the cylinder and negative end of the hot carbon filament were measured by a potentiometer. The effective resistance of the vacuous space is then taken to be the ratio of the so observed potential difference (valve P.D.) to the current (valve current) through the vacuum.

The following table records the observations. The column headed P.D. gives the potential difference between the hot filament and the cylinder, that headed A gives the current through the vacuous space in milliampères, that headed R the resistance of the space in ohms, and that headed $K10^5$ is 100,000 times the conductivity.

The result is to show that the vacuous space does not possess a constant resistance, but its conductivity increases rapidly up to a maximum and then decreases as the valve potential difference progressively increases. If we plot the current values as ordinates and potential difference of the valve electrodes as abscissæ, we find that the current curve quickly rises to a maximum value and then falls again slightly as the potential difference increases steadily. The conductivity curve also rises to a maximum and then decreases (see fig. 3).

The facts so exhibited are well-known characteristics of gaseous

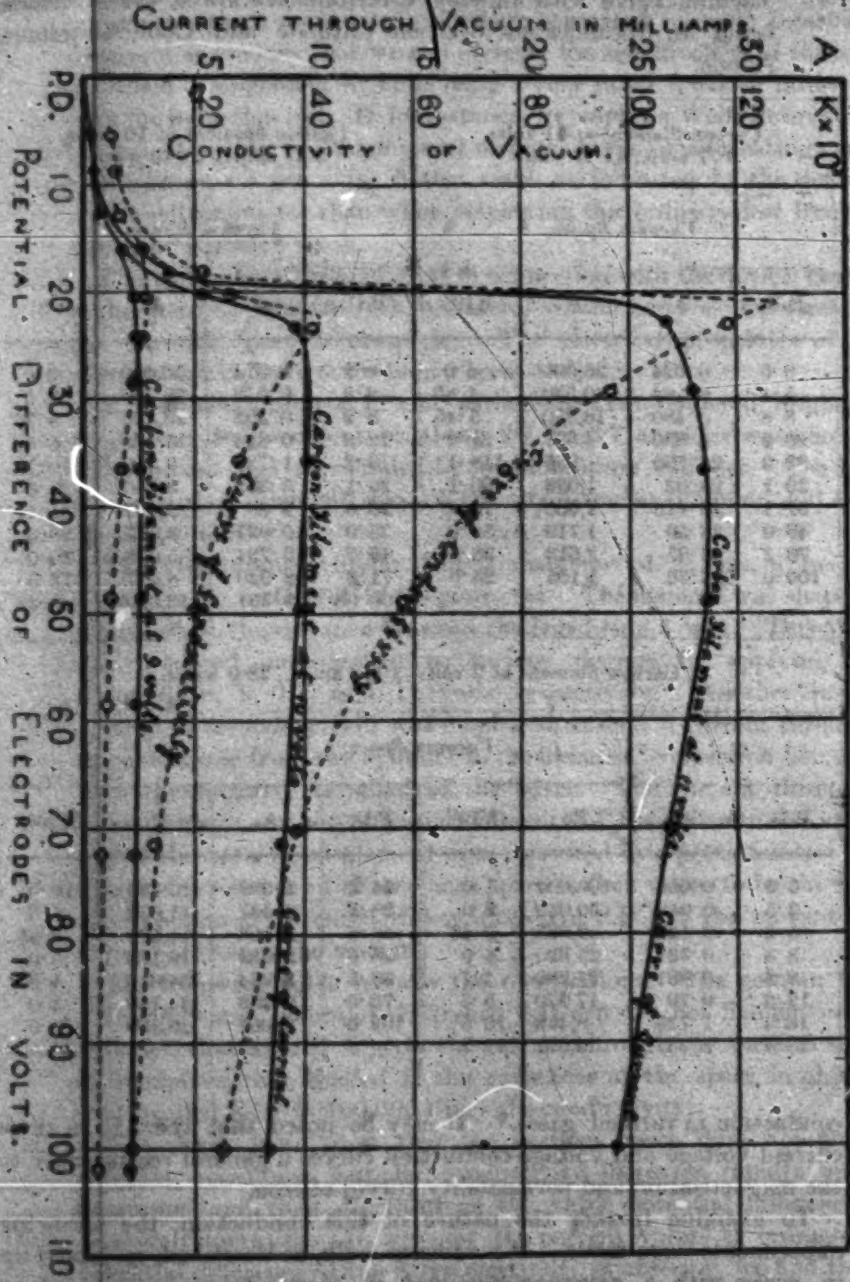
conduction in rarified gases.* It may be noted that there is in these current-voltage and voltage-conduction curves a general resemblance to the magnetisation and permeability curves of iron.

To examine further the nature of this conduction, the following experiments were made. If a vacuum bulb, as described, is joined up in series with a galvanometer and an electrodynamometer and an alternating electromotive force applied to the circuit, the two instruments will both be affected. The galvanometer is, however, affected only by

---

* See J. J. Thomson, 'Conduction of Electricity through Gases,' Chap. VIII.

FIG. 3.



the resultant flux of electricity in one direction. It measures the unidirectional current. The dynamometer is affected by the bilateral flux of electricity and it measures the total or alternating current. If, therefore, the vacuous space is totally non-conducting in one direction, one half of the alternating current will be cut out. The galvanometer will read the true mean (T.M.) value of the remanent unidirectional current, and the dynamometer will read the root-mean-square (R.M.S.) value. If the conductivity in one direction is not zero, then the galvanometer will read the T.M. value of the difference of the positive and negative currents, but the dynamometer will read the R.M.S. value of their sum.*

In the last case, the current through the valve may be considered to be a continuous current superimposed upon an alternating current.

If we call I the maximum value of the nearly sinoidal current in one direction, and I′ the maximum in the opposite direction, then we may say that the dynamometer reading (D) expressed in true current value is equal to $g\,(I+I')$ where g is the *amplitude factor*, and also that the galvanometer reading (G) in true current value is equal to $g/f\,(I-I')$ where f is the *form factor* of the current.† Hence—

$$\frac{D}{G} = f\frac{I+I'}{I-I'}, \text{ or } \frac{D/G+f}{2f} = \frac{I}{I-I'}.$$

The fraction $\frac{2f}{D/G+f}$, say β, expressed as a percentage may be called the *rectifying power* of the valve, for it expresses the percentage which the actual unilateral electric flow or continuous current through the valve is of that continuous current which would flow if the unilateral conductivity were perfect.

Perfect rectifying power, however, does not exist. There is not an infinite resistance to movement of negative electricity from the metal cylinder to the hot filament through the vacuum, although this resistance is immensely greater than that which opposes the movement of negative electricity in the opposite direction. This point was examined, as follows: A very sensitive electrodynamometer was skilfully constructed by my assistant, Mr. G. B. Dyke, the fixed coil having 2000 turns of No. 47 silk-covered copper wire and the movable coil 1000 turns. The suspension of the movable coil was by a fine flat phosphor-bronze wire at top and bottom. The deflection was observed by a mirror and scale.

---

* If i is the instantaneous value of a periodically varying current with maximum value I and periodic time T, then the root-mean-square value (R.M.S. value) of i is defined to be $\left(\frac{1}{T}\int_0^T i^2 dt\right)^{\frac{1}{2}}$ and the true mean value (T.M. value) of i is defined to be $\frac{2}{T}\int_0^{\frac{1}{2}T} i\,dt$.

† The *form factor f* and *amplitude factor g* are the names given by the author (see 'Alternating Current Transformer,' J. A. *Fleming*, vol. 1, p. 585, 3rd edit.) to the ratio of the R.M.S. to the T.M. value of the ordinates of a single valued periodic curve, and to the ratio of the R.M.S. value of the ordinates to the maximum value during the period.

This dynamometer was placed in series with a shunted movable coil galvanometer of Holden-Pitkin pattern, and the two together placed in series with a variable section of an inductionless coil through which an alternating current was passing. A vacuum valve as above described was in series also with the galvanometer and dynamometer. The alternating current was derived from an alternator giving a nearly true sinoidal electromotive force. The form factor of the electromotive force curve of this alternator was determined and found to be 1·115, that for a true sine curve being 1·111.

The vacuum valve sifted out the alternating current flow and allowed the currents in one direction to pass, but nearly stopped those in the opposite direction. The indications of the electrodynamometer were proportional to the root-mean-square (R.M.S.) value of the sum of the two opposite currents, and that of the galvanometer to the true mean value (T.M.) of their difference. The galvanometer and dynamometer were both calibrated by a potentiometer by means of continuous current, and curves constructed to convert their scale readings to milliampères. Then with various alternating current electromotive forces, their readings were taken when in series with a vacuum valve and recorded in the following tables. The letter D denotes current in milliampères as read by the so calibrated dynamometer and G that read by the galvanometer. The ratio D/G is denoted by z, and the rectifying power, viz., $2/z+1$ by β.

The table shows that the value of z is not constant, but for each state of incandescence of the filament reaches a maximum which, however, does not greatly differ from the mean value for the range of currents used. If we set out the mean values of β in a curve (see fig. 4), in terms of the power expended in heating the carbon filament, we see that the rectification is less complete in proportion as the temperature of the carbon filament increases. This is probably due to the fact that as the filament gets hotter, it heats the enclosing cylinder to a higher temperature and enables negative electricity to escape from the latter.

Hence, I feel convinced that if the metal cylinder could be kept quite cool by water circulation the rectification would reach 100 per cent. or be complete.

An ideal and perfect rectifier for electric oscillations may, therefore, be found by enclosing a hot carbon filament and a perfectly cold metal anode in a very perfect vacuum. With a bulb such as that used for the above experiments all we can say is that the current passed through the vacuum is from 80 to 90 per cent. continuous, 100 per cent. implying that the vacuum is perfectly non-conducting in one direction and permits the flow of negative electricity only from the hot to the cold electrode. The necessity for keeping the cathode cold is shown by the following experiment:—An alternating-current arc was

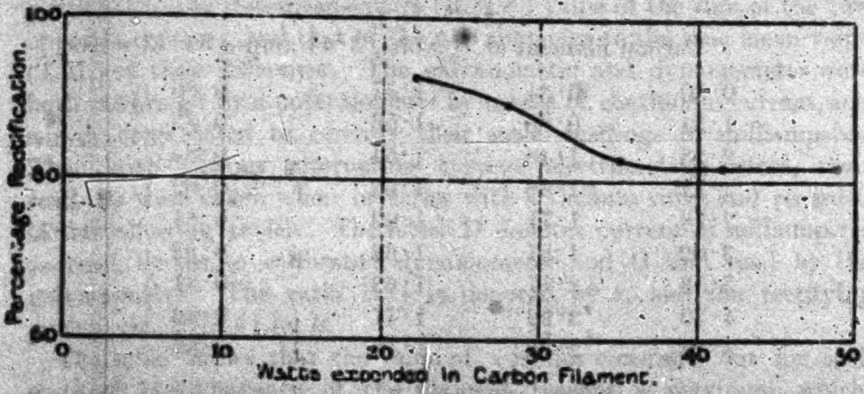
formed between carbon rods, and an iron rod was placed so that its end dipped into the arc. An ammeter was connected in between either carbon and the iron rod, and indicated a continuous current of negative electricity flowing through the ammeter from the iron rod to the carbon pole. This current was, however, greatly increased by making the iron rod of a piece of iron pipe closed at the end and kept cool by a jet of water playing in the interior. In this manner I have been able to draw off a continuous current of 3 or 4 amperes from an alternating-current arc using 15 alternating-current ampères.

Returning, then, to the vacuum valve, we may note that the curves in fig. 3 show that the vacuous space possesses a maximum conductivity corresponding to a potential difference of about 20 volts between the electrodes, for the particular valve used. The interpretation of this fact may, perhaps, be as follows:—In the incandescent carbon there is a continual production of electrons or negative ions by atomic dissociation. Corresponding to every temperature there is a certain electronic tension or percentage of free electrons. If the carbon is made the negative electrode in a high vacuum these negative ions are expelled from it, but they cannot be expelled at a greater rate than they are produced. Therefore, there is a maximum value for the outgoing current and a maximum value for the ratio of current to electromotive force, that is for the conductivity.

Fig. 4.



This fact, therefore, fixes a limit to the utility of the device. The current through the vacuous space is, to a very large extent, independent of the electromotive force creating it, and is at no stage proportional to it, or at least only within a narrow range of electromotive force near to the maximum conductivity.

Whilst, therefore, the device is useful as a simple means of detecting electric oscillations, it has not that uniformity of conductivity which would make it useful as a strictly metrical device for measuring them. It can, however, perform the useful service of showing us how far any device for producing electric oscillations or electric waves produces a uniform or very irregular train of electric oscillations, and what changes conduce to an improvement or reduction in the efficiency of the transmitting device.

UNITED STATES PATENT OFFICE.

JOHN AMBROSE FLEMING, OF LONDON, ENGLAND, ASSIGNOR TO MARCONI WIRELESS TELEGRAPH COMPANY OF AMERICA, A CORPORATION OF NEW JERSEY.

INSTRUMENT FOR CONVERTING ALTERNATING-ELECTRIC CURRENTS INTO CONTINUOUS CURRENTS.

No. 803,684. Specification of Letters Patent. Patented Nov. 7, 1905.

Application filed April 19, 1905. Serial No. 256,488.

To all whom it may concern:

Be it known that I, JOHN AMBROSE FLEMING, professor of electrical engineering, a subject of the King of Great Britain, residing at University College, Gower street, London, in the county of Middlesex, England, have invented certain new and useful Improvements in Instruments for Converting Alternating Electric Currents into Continuous Currents, of which the following is a specification.

This invention relates to certain new and useful devices for converting alternating electric currents, and especially high-frequency alternating electric currents or electric oscillations, into continuous electric currents for the purpose of making them detectable by and measurable with ordinary direct-current instruments, such as a "mirror-galvanometer" of the usual type or any ordinary direct-current ammeter. Such instruments as the latter are not affected by alternating electric currents either of high or low frequency, which can only be measured and detected by instruments called "alternating-current" instruments of special design. It is, however, of great practical importance to be able to detect feeble electric oscillations, such as are employed in Hertzian-wave telegraphy by an ordinary movable coil or movable needle mirror-galvanometer. This can be done if the alternating current can be "rectified"—that is, either suppressing all the constituent electric currents in one direction and preserving the others or else by changing the direction of one of the sets of currents which compose the alternating current so that the whole movement of electricity is in one direction. Many means have been devised and are in use for rectifying low frequency alternating currents, such as are used in electric lighting. There are well-known forms of mechanical rectifier; also, there is a well-known form of electrochemical rectifier, depending on the fact that when a plate of carbon and aluminium is placed in any electrolyte which yields oxygen on electrolysis an electric current can only pass through this cell in one direction if below a certain voltage. Both these forms of rectifier are, however, inapplicable for high-frequency currents. I have found that the aluminium-carbon cell will not act with high-frequency currents.

I have discovered that if two conductors are inclosed in a vessel in which a good vacuum is made, one being heated to a high temperature, the space between the hot and cold conductors possesses a unilateral electric conductivity, and negative electricity can pass from the hot conductor to the cold conductor, but not in the reverse direction. As the hot conductor should be heated to a very high temperature—say near to the melting-point of platinum, (1,700° centigrade)—it should be of carbon, preferably in the form of a filament such as is used in any ordinary incandescent electric lamp. The cold conductor may be of many materials; but I prefer a bright metal, such as platinum or aluminium or else carbon. The two conductors are inclosed in a glass bulb similar to that of an incandescent lamp, and I generally heat the carbon filament to a high state of incandescence by a continuous electric current, the electrical connection to the filament and the cold conductor being made by platinum wires, sealed air-tight through the glass.

Figure 1 is a full-size sectional elevation of an instrument constructed according to this invention, the electrical connections being shown diagrammatically. This figure illustrates the application of the invention to wireless telegraphy. Figs. 2 and 3 show modifications to smaller scales.

In Fig. 1, *a* is a glass bulb, and *b* is a carbon filament like the carbon filament of an incandescent lamp, suitable, say, for taking a current of six to eight volts and two to four amperes. *c* is a cylinder of aluminium, open at the top and bottom, which surrounds but does not touch the filament. The cylinder *c* is suspended and steadied by platinum wires *d*, and the ends of the filament *b* are connected to platinum wires connected to the leads *e* and *f*. The platinum wires are sealed through the glass in the ordinary manner.

As a very high vacuum should be obtained in the bulb *a* and as a considerable quantity of air is occluded in the conductors, these should be heated when the bulb is being exhausted. The filament *b* can be conveniently heated by passing a current through it, while the cylinder *c* can be heated by surrounding the bulb *a* with a resistance-coil through which a current is passed, the whole being inclosed in a box lined with asbestos or the like. When, as hereinafter described, the cylinder *c* is replaced by any form of conductor which can be heated by passing a current through it, this method is usually more convenient than that just described.

The carbon filament is made highly incandescent in the usual way by a continuous electric current produced by the battery *h*, the negative pole of which is connected to the wire *e* and the positive to the wire *f*. The wires *d* and *e* are connected together by a wire *j*, which completes the circuit through the secondary winding *k* of an induction-coil (such as is ordinarily used in wireless telegraphy) and a galvanometer *l*.

m is the primary winding of the induction-coil, having one end connected, as is usual, to an aerial wire *n* and the other to earth *o*. The arrangement described above operates as an electric valve and permits negative electricity to flow from the hot carbon *b* to the metal cylinder *c*, but not in the reverse direction, so that the alternations induced in the coil *k* by the Hertzian waves received by the aerial wire *n* are rectified or transformed into a more or less continuous current capable of actuating the galvanometer *l* by which the signals can be read.

Although Fig. 1 shows the application of the instrument to wireless telegraphy, it will be understood that the aerial wire *n* may be replaced by any circuit in which there is an alternating electromotive force, whether of low frequency or of high frequency.

I may increase the effect in the following manner: I employ two bulbs arranged as shown in Fig. 2, each being similar to that shown in Fig. 1. *p p* are the two coils of a differential galvanometer connected to the bulbs in such fashion that currents flowing in opposite directions through the two bulbs flow in the same direction round the two coils of the galvanometer as regards the needle *q* of the galvanometer itself. For this purpose the hot conductor of each bulb is connected to the cold conductor of the other. Hence one bulb permits negative electricity to flow only in one direction and the other bulb permits only negative electricity to flow in the opposite direction through it. The common terminal of the two galvanometer-coils *p* is connected to the coil *k* or any source of alternating electromotive force or of electrical oscillations, the other terminal of the said source being connected to the bulbs, as shown. Each bulb has its own separate insulated battery *h* for heating its hot filament. Under these circumstances alternating electric currents are split into two continuous currents passing through the two bulbs in opposite and in the two coils of the galvanometer in the same directions. By thus using a differential galvanometer I make use of the whole of the energy of the alternating current instead of discarding half of it. In this manner very feeble electrical oscillations can make themselves apparent by the indication which they give on a sensitive mirror-galvanometer. A number of these valves may be associated together in parallel, as shown in Fig. 3, so that alternating currents rectified by them separately may produce continuous currents which are added together.

In place of using a metal cylinder surrounding a carbon-loop filament I sometimes use a number of carbon filaments. Some of these are heated by means of an electric current and become the hot conductor of the oscillation-valve and the others remain cold and form the cold conductor, or the metal cylinder may be replaced by a cylinder of meerschaum or the like having wound helically upon it a narrow ribbon of metallic foil. In those cases in which a larger alternating current has to be dealt with the hot conductor may be a rod of soft graphitic carbon held in suitable supports.

I find it possible by means of the device described above to rectify an alternating current without the use of any auxiliary continuous heating-current. Thus if I pass through the carbon filament an alternating current to bring it to bright incandescence I find if I connect either terminal of the filament by a circuit outside the bulb with the terminal of the embracing cylinder or other cold-conductor then in this circuit a continuous current flows. Hence the device may be used for rectifying either high-frequency or low-frequency alternating currents of electrical oscillations, provided these are of sufficient strength to render a carbon filament brilliantly incandescent.

It will be understood that when an alternating current is impressed upon a circuit including one of my improved rectifiers, as in Fig. 1, the alternating impulses in one direction will be suppressed and the alternating pulsations in the other direction will pass through the circuit in the form of a pulsating unidirectional current. This pulsating unidirectional current actuates the galvanometer or other continuous-current-indicating instrument *l*. When two rectifiers are used oppositely connected, as in Fig. 2, there will result two unidirectional pulsating currents flowing in opposite directions, and both of these currents are utilized in the differential galvanometer.

When I specify in my claims "means for detecting a continuous current" I intend to include any instrument for detecting such a single unidirectional pulsating current or two such unidirectional pulsating currents flowing in opposite directions.

What I claim is—

1. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for heating one of the conductors, and a circuit outside the vessel connecting the two conductors.

2. The combination of a vacuous vessel, two

conductors adjacent to but not touching each other in the vessel, means for passing an electric current through one of the conductors, and a circuit outside the vessel connecting the two conductors.

3. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for heating one of the conductors, a circuit outside the vessel connecting the two conductors, means tending to produce an alternating current in the circuit, and means for detecting a continuous current in it.

4. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for passing an electric current through one of the conductors, a circuit outside the vessel connecting the two conductors, means tending to produce an alternating current in the circuit, and means for detecting a continuous current in it.

5. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for passing a continuous electric current through one of the conductors, and a circuit outside the vessel connecting the two conductors.

6. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for passing a continuous electric current through one of the conductors, a circuit outside the vessel connecting the two conductors, means tending to produce an alternating current in the circuit, and means for detecting a continuous current in it.

7. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for heating one of the conductors, a circuit outside the vessel connecting the two conductors, an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth, and means for detecting a continuous current in the circuit.

8. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for passing an electric current through one of the conductors, a circuit outside the vessel connecting the two conductors, an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth, and means for detecting a continuous current in the circuit.

9. The combination of a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for passing a continuous electric current through one of the conductors, a circuit outside the vessel connecting the two conductors, an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth, and means for detecting a continuous current in the circuit.

10. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surrounding but not touching the filament, means for heating the filament, and a circuit outside the vessel connecting the filament to the cylinder.

11. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surrounding but not touching the filament, means for passing an electric current through the filament, and a circuit outside the vessel connecting the filament to the cylinder.

12. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surroupding but not touching the filament, means for heating the filament, a circuit outside the vessel connecting the filament to the cylinder, means tending to produce an alternating current in the circuit, and means for detecting a continuous current in it.

13. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surrounding but not touching the filament, means for passing an electric current through the filament, a circuit outside the vessel connecting the filament to the cylinder, means tending to produce an alternating current in the circuit, and means for detecting a continuous current in it.

14. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surrounding but not touching the filament, means for passing a continuous electric current through the filament, and a circuit outside the vessel connecting the filament to the cylinder.

15. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surrounding but not touching the filament, means for passing a continuous electric current through the filament, a circuit outside the vessel connecting the filament to the cylinder, means tending to produce an alternating current in the circuit, and means for detecting a continuous current in it.

16. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surrounding but not touching the filament, means for heating the filament, a circuit outside the vessel connecting the filament to the cylinder, an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth, and means for detecting a continuous current in the circuit.

17. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surrounding but not touching the filament, means for passing an electric current through the filament, a circuit outside the vessel connecting the filament to the cylinder, an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth, and means for detecting a continuous current in the circuit.

18. The combination of a vacuous vessel, a carbon filament in the vessel, a metallic cylinder surrounding but not touching the filament, means for passing a continuous electric current through the filament, a circuit outside the vessel connecting the filament to the cylinder, an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth, and means for detecting a continuous current in the circuit.

19. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, and a circuit connecting the two latter connections.

20. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for passing an electric current through and so heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, and a circuit connecting the two latter connections.

21. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for passing a continuous electric current through and so heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, and a circuit connecting the two latter connections.

22. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, a circuit connecting the two latter connections, and means tending to produce an alternating current in the circuit.

23. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for passing an electric current through and so heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, a circuit connecting the two latter connections, and means tending to produce an alternating current in the circuit.

24. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for passing a continuous electric current through and so heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, a circuit connecting the two latter connections, and means tending to produce an alternating current in the circuit.

25. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for heating the filaments, two coils of a differential galvanometer one coil being connected to the filament in one vessel and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, and a circuit connecting the two latter connections.

26. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for passing an electric current through the filaments, two coils of a differential galvanometer one coil being connected to the filament in one vessel and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, and a circuit connecting the two latter connections.

27. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for passing a continuous electric current through the filaments, two coils of a differential galvanometer one coil being connected to the filament in one vessel and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, and a circuit connecting the two latter connections.

28. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for heating the filaments, two coils of a differential galva-

nometer one coil being connected to the filament in one vessel and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, a circuit connecting the two latter connections, and means tending to produce an alternating current in the circuit.

29. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for passing an electric current through the filaments, two coils of a differential galvanometer one coil being connected to the filament in one vessel and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, a circuit connecting the two latter connections, and means tending to produce an alternating current in the circuit.

30. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for passing a continuous electric current through the filaments, two coils of a differential galvanometer one coil being connected to the filament in one vessel, and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, a circuit connecting the two latter connections, and means tending to produce an alternating current in the circuit.

31. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, a circuit connecting the two latter connections, and an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth.

32. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for passing an electric current through and so heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, a circuit connecting the two latter connections, and an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth.

33. The combination of two vacuous vessels, two conductors adjacent to but not touching each other in each vessel, means for passing a continuous electric current through and so heating one of the conductors in each vessel, two coils of a differential galvanometer, one coil being connected to the heated conductor in one vessel and the other coil being connected to the unheated conductor in the other vessel, a connection between the other pair of conductors, a connection between the coils, a circuit connecting the two latter connections, and an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth.

34. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for heating the filaments, two coils of a differential galvanometer one coil being connected to the filament in one vessel and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, a circuit connecting the two latter connections, and an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth.

35. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for passing an electric current through the filaments, two coils of a differential galvanometer one coil being connected to the filament in one vessel and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, a circuit connecting the two latter connections, and an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth.

36. The combination of two vacuous vessels, a carbon filament in each vessel, a metallic cylinder in each vessel, surrounding but not touching the filament, means for passing a continuous electric current through the filaments, two coils of a differential galvanometer one coil being connected to the filament in one vessel and the other coil being connected to the cylinder in the other vessel, a connection between the other cylinder and filament, a connection between the coils, a circuit connecting the two latter connections, and an induction-coil having its secondary winding in the circuit and its primary winding connected to an aerial wire and earth.

37. At a receiving-station in a system of wireless telegraphy employing electrical os-

cillations of high frequency a detector comprising a vacuous vessel, two conductors adjacent to but not touching each other in the vessel, means for heating one of the conductors, a circuit outside of the vessel connecting the two conductors, means for detecting a continuous current in the circuit, and means for impressing upon the circuit the received oscillations.

ON THE ELECTRIC CONDUCTIVITY OF A VACUUM.*

By J. A. FLEMING, M.A., D.Sc., F.R.S.

In the thirteenth series of his Experimental Researches on Electricity, Faraday discusses the question whether a vacuum should be considered to be a conductor or a non-conductor of electricity. The subject may seem, to some people, to be of purely academic interest, and devoid of any technical value. Since, however, any increase in knowledge concerning the manner in which electricity is moved from place to place, and its relation to atoms of matter, is extremely practical, the consideration of the conductivity of a so-called vacuum is not an unimportant matter. Since the time of Faraday we have been able to make vacua far more complete than any attained by him. Nevertheless, any vacuum we can make can only be so called by courtesy. In air at ordinary pressure there are about 10^{20} molecules per cubic centimeter; hence, even

---

* Technics.

if we can take out from any space all but one hundred-millionth of the original gas at atmospheric pressure, the molecular population of that space must still be very large. Sir James Dewar has shown that extremely high vacua can be most rapidly produced by condensing the residual air in an ordinary vacuum by cocoanut charcoal, cooled by liquid hydrogen, and it may be possible in this way to remove from any space all but a very small proportion of the gaseous matter present.

Let us assume that we make a high vacuum of one hundred-millionth, of an atmosphere in a glass vessel and that in it are placed two metal plates, say of platinum, at a distance of a millimeter apart. Let these plates be connected to platinum wires sealed through the glass. If the plates are cold, it is then possible to create between them a difference of potential of 100,000 volts or so, and yet not cause any discharge or the slightest measurable current across the space. A vacuum can be made such that an induction coil giving a spark of several centimeters length in air will not strike across a space of one millimeter in the vacuum between cold metal terminals. This fact at first sight appears to show that a high vacuum is a very perfect non-conductor, and this opinion has generally been held.

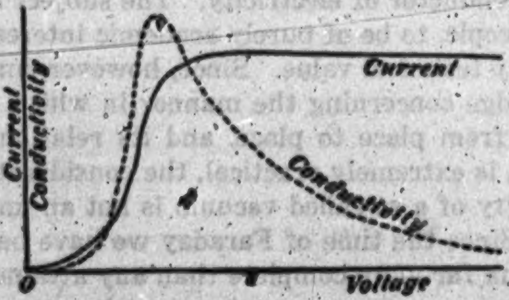

Fig. 8.—Curve Showing the Variation of Current and Conductivity through the Vacuum Valve, with Increasing Potential Difference between the Electrodes.

If, however, we modify the experiment slightly, we shall be able to show that the highest vacuum we can produce may, under other conditions, be a very good conductor.

Imagine a bulb of glass, made as in Fig. 1, containing two loops of platinum wire, or better still, two carbon filaments. Let this bulb be exhausted as completely as possible, so that in it the highest attainable vacuum is made. To achieve this, the filaments must be heated to bright incandescence while the exhaustion is going on. Having done this, if the secondary terminals of an induction coil are connected to the two separate filaments when cold, no discharge will take place across the vacuum be-

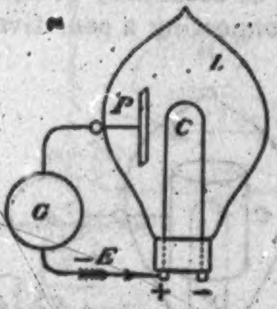

FIG. 4.

tween them, thus apparently showing that the space is a very perfect non-conductor. Suppose, however, that we render one or both of these filaments incandescent by passing electric currents through them by means of two insulated batteries of secondary cells, S^1, S^2 (Fig. 2), it will be found, on connecting a sensitive galvanometer, *G*,

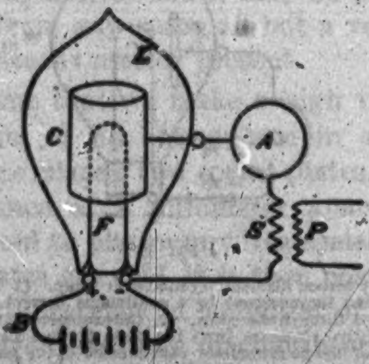

Fig. 6.—Vacuum Valve for Rectifying Electrical Oscillations.

and a single cell, *S*, as a shunt to the two negative terminals of the two separate filaments, that a current of several milliamperes will pass across the vacuum under the electromotive force of this single cell. The arrangements should be as shown in Fig. 2. If only one of the filaments is ignited, and if it is that in connection with the negative terminal of the single cell in the shunt circuit, then the current still passes; but if the other filament alone is ignited, no current, or only a very much smaller current passes. The same experiment can be repeated using platinum loops instead of carbon filaments, and it shows that a high vacuum may be a very good conductor, provided that the negative electrode is rendered incandescent. This shows that the obstruction which a high vacuum offers to the passage of electricity is not due to the mere reduction of the matter in the space (that is, to the rarefaction of the gas), but is, in

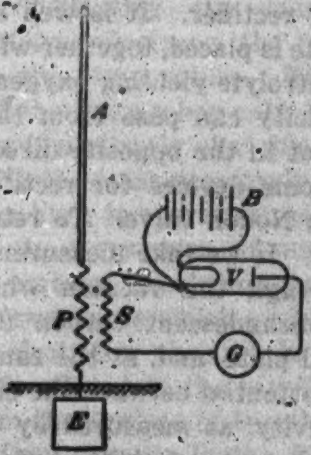

Fig. 7.—Vacuum Valve Used as Receiver in Wireless Telegraphy.

A. Aerial wire. P, S. Oscillation transformer. V. Vacuum valve. B. Battery. G. Galvanometer.

some way or other, largely dependent upon the temperature of the electrodes; the resistance to the passage of electricity through a vacuum can be rendered very small by intensely heating the negative electrode. Hence, such a bulb containing two carbon filaments forming the two electrodes, one of which can be rendered incandescent, will act as a *vacuum-valve*, allowing the electricity to pass in one direction, but not in the other. It permits negative electricity to pass out of the hot electrode, but not out of the cold electrode. If, in place of a single secondary cell (arranged in the shunt circuit, as in Fig. 2, to give a direct current), we employ an alternator, giving an alternating current, but still keep the galvanometer in the circuit, we shall find, as was first shown by the writer in 1889, that a continuous current passes through the gavanometer; in other words, the vacuum possesses a unilateral conductivity, and separates out the two constituents of the alternating current, passing one but not the other. This fact was first demonstrated and described in a paper by the author of this article, presented to the Royal Society in 1889.

In this respect, such a vacuum valve resembles an aluminium-carbon rectifier. It is well known that, if a carbon or iron plate is placed, together with an aluminium plate, in some electrolyte yielding oxygen, then a current of positive electricity can pass from the carbon to the aluminium, but not in the opposite direction. This fact is the basis of some devices for rectifying alternating current, such as a Nodon valve. To return, however, to the vacuum valve. If we take measurements of the current passing through the vacuum when the negative electrode is an incandescent carbon filament and the other a cold metal plate, and, at the same time, measure the difference of potential between the electrodes, we find that the conductivity, as measured by the ratio of current to voltage, is not constant, but varies with the electromotive force. In other words, the resistance of the vacuous space does not follow Ohm's law. As the electromotive force is steadily increased, the current gradually increases up to a certain maximum, and then slightly falls again. The firm line curve in Fig. 3 shows the general relation between current and voltage up to 100 volts; and it will be noticed that the curve is something like a magnetization curve of iron. It follows that the curve of conductivity, represented by the dotted line, is a curve rising rapidly to a maximum, and resembling to some extent the curve of permeability of iron.

For an explanation of these facts we must fall back upon the electronic hypothesis of matter and electricity. According to this view, atoms of matter are built up of electrons, which are point-charges of electricity; and an atom is considered to be made up either of a collocation of positive and negative electrons in orbital motion round one another, or else of negative electrons, or simply of electrons scattered throughout a space, which in some way or other, not yet understood, constitutes a sphere of positive electricity. In any case, facts connected with electro-chemistry and radio-activity show that atoms can break up, by giving off electrons, or can part with one or more electrons. Hence, in any mass of matter, such as a metal, there must be, in addition to the complete atoms or molecules constituting the mass, a distribution throughout it of free electrons, the percentage of these increasing with the temperature. These electrons cannot escape from the mass when cold, because if they did they would leave it positively electrified. If, on the other hand, we electrify the mass negatively to a high potential and raise it to a high temperature, electrons can escape freely from it. In every mass of matter there is what we may call a certain "electronic pressure"; hence, it follows that the resistance which a high vacuum offers to the passage of electricity through it is, in fact, the resistance which is offered to the ejection or drawing out of electrons from the surface of the electrodes.

In an interesting paper in the Philosophical Magazine for October, 1904, Lord Kelvin sums up the position as follows: "The labors of many experimenters during the last fifty years, and the comparatively modern atomic theory of electricity have thoroughly confirmed the view that the space of our best modern vacua, interstellar and interplanetary space, and generally, space occupied only by the luminiferous æther, is a very perfect non-resister of electricity passing through it. Hence, we see that the insulation of electricity in a vacuum is to be explained, not by any resistance of vacant space or of æther, but by a resistance of glass or metal or other solid or liquid against the extraction of electrions* from it, or against the tearing away of electrions or fragments of its own substance."

Lord Kelvin enters into some calculations of a very interesting kind, estimating the force required to extract an electron from the negative electrode. He considers an atom to consist of a sphere of positive electricity (it may be of positive electrons distributed through a spherical space), and he calculates the force necessary to tear a negative electron out of this environment. The force required to displace the negative electron whose charge is

---

* Lord Kelvin uses the term *electrion* for an infinitely small point-charge or atom of negative electricity. Most other writers, following the suggestion orginally made by Professor Johnstone Stoney, call these point-charges of electricity *electrons*.

e by a distance, x, from its position at the center of an atom whose radius is r, is equal to ex/r^2 electrostatic units. Now, the charge carried by one electron is known to be 3.4×10^{-10} electrostatic units, and the radius of an atom is known to be of the order of 10^{-8} centimeter. Hence, the force required to make $x/r = 1/9$ or to move an electron from the center of the atom only one-ninth part of the way to the atomic surface, is 320,000 electrostatic units, or equal to 96 million volts per centimeter; and the force required to extract the electron altogether would be equal to 384 million volts per centimeter.

This, as Lord Kelvin shows, means a strain equal to 66.4 tons per square centimeter, and would rupture or pull apart the strongest steel.

It seems, therefore, clearly impossible for any electrostatic force which we can create, to directly break up atoms or draw out electrons from them. On the other hand, it is a cardinal principle in the electronic theory of electricity, that the only way in which an electric current can be produced is by the movement of electrons. Since, therefore, we can produce currents of electricity in conductors by feeble electromotive forces, it follows that free electrons must exist within the metal. We picture to ourselves, therefore, a mass of metal as follows:

It is composed of atoms, each one of which is a complex structure of electrons in motion and vibration. Owing to collisions and mutual reactions, electrons are detached from some atoms, and constitute free point-charges of negative electricity, which remain mixed up with the atoms. The remainder of the atom from which the electron is detached is therefore positively charged, and may be called a positive ion. The free electrons are continually being set free from atoms, and taken up again by others. Hence, at any one moment there is a certain percentage of complete atoms and a certain corresponding percentage of free electrons and positive ions. The equilibrium is dynamic, and no doubt determined by temperature. The free electrons can move about between the atoms and comport themselves like molecules of gas in a vessel. They cannot leave the metal, because, if they did, it would be positively electrified. Hence, any attempt of an electron to remove itself from the conductor is strongly resisted. On the other hand, the electrons diffuse from one place to another in the same mass, if by any reason the concentration of electrons is different at the two places.

Creating an electromotive force in a metallic mass merely means that we make a difference in concentration or density of free electrons between different places, or that the number per cubic centimeter is greater at one place than at the other. Then there is a tendency for electrons to migrate or diffuse from the place where they are most numerous to places where they are less numerous. This diffusion of electrons constitutes an electric current. Electronic movement under variation of concentration follows the same laws as the diffusion of solids in solutions. This law, moreover, when mathematically considered, leads at once to the well-known law of Ohm defining the current under various electromotive forces in a conductor.

Suppose, then, that we seal two platinum wires into the opposite ends of a glass tube, and connect these two wires to a battery, or induction coil, or transformer. These appliances are virtually electron pumps, and force an excess of electrons into one piece of platinum and make a deficit in the other. The one which has an excess of electrons is the negative electrode. If the pressure is great enough, electrons may be projected from the negative electrode. If, however, the electrode is surrounded by air molecules at normal air pressure, the electrons projected from the metal never attain a very high velocity.

Imagine, now, the gas molecules greatly reduced in number—in other words, the air in the bulb rarefied and a "vacuum" made.

We have three broadly marked conditions to consider. We may have the "vacuum" low or high. We may have the electrodes cold or incandescent. We may have the electronic pressure difference, or voltage between, them, small or large.

Let us define these conditions more closely.. The vacuum is said to be low when the original normal air pressure in it is reduced to one-thousandth of an atmosphere, or it may be only to one three-hundredth. It is said to be high when it is reduced to one hundred-millionth of an atmosphere. The electrodes are said to be cold when not in any way specially heated. They are incandescent when brought to a bright white heat by some external means. The voltage is said to be small when the difference of potential between the electrodes is only a volt or two. It is said to be large when it is some hundreds or thousands of volts.

The phenomena which take place when the "vacuum" is not very high (that is, when the residual gas pressure is only about one-thousandths of an atmosphere), and the electrodes are cold, are very complicated. In this case we have an enormous number of gaseous atoms per cubic centimeter still left, and we have all the beautiful but complex phenomena shown by an ordinary *vacuum tube,* provided the potential difference of the electrodes is made sufficiently great (that is, provided it amounts to some hundreds or thousands of volts). The study of these phenomena has given occupation to a large number of the most distinguished physicists, and it has taken them at least have a century to unravel them. When the vacuum is very high (that is, if the residual gas pressure is something less than one ten-millionth of an atmosphere) the phenomena becomes simplified. We then observe the well-known effects of the Crookes or Röntgen tube. The electrons in the negative electrodes are projected from it, owing to the great electric force, with very high velocities; and as their path is not sensibly disturbed by the sparsely distributed molecules of the remanent gas, we have all the phosphorescent and other remarkable effects due to the bombardment of these electrodes, and their impact gainst the glass walls of the vessel or objects placed in the tube. This state makes itself evident by the apple-green phosphorescence of the glass vessel.

We may have a third set of conditions. If the negative electrode is heated to a very high temperature, then even if the electric potential of this electrode is low (that is, if there is only a volt or less difference of potential between the two electrodes) we have a very considerable current of electricity passing across a very highly vacuous space.

This can only be accounted for by the fact that the incandescent carbon or metal which forms the negative electrode is emitting vast numbers of these electrons or point-changes of negative electricity. These are flung out of the heated metal by the high velocities which they attain. Just as it would be possible to impart to a projectile such a velocity as would carry it beyond the earth's attraction, so the electrons present in the metal, when its temperature is high enough, are flung out of the mass; and if that mass is kept at a high potential this torrent of negatively charged electrons is a current of electricity.

We have in these facts an explanation of many well-known phenomena. One effect in the case of incandescent electric lamps has been much studied by the author; as it was first noticed by Mr. Edison, it is usually called the Edison effect. A plate of platinum or other metal, *P*, is attached to a platinum wire, and this last is sealed into the bulb of an incandescent lamp, *L*. The plate is placed as shown in Fig. 4. If then, the filament is rendered incandescent by a continuous current, and if we connect a sensitive galvanometer, *G*, between the positive terminal of the filament and the terminal of the plate, we find a current of several milliamperes passing through it. If, however, we connect the galvanometer between the negative terminal and the plate, no current flows. Again, if we render the filament incandescent by an alternating current, we can draw off a continuous current by connecting a galvanometer between the plate terminal and either of the terminals of the filament. These phenomena are susceptible of explanation by the fact that negative electricity (that is, electrons) can escape freely from the hot carbon filament, and hence move across the high vacuum and enter the positively electrified plate. The same thing can be shown with an electric arc. The writer showed many years ago, that if a thin carbon rod (or better still, an iron tube, *M*, closed and made chisel-shaped at one end, and cooled by water led into the interior) is placed with its sharp end just dipping into the electric arc, then a continuous current can be drawn off by a wire connecting this third pole with the positive carbon of the arc, and rendered evident on an ammeter, *A* (see Fig. 5).

On the other hand, no current, or very little current, passes through a wire connecting the negative carbon and this middle pole; or, if the arc is formed with an alternating current of electricity, in a wire which connects either carbon to a cool middle pole dipping into the arc.

These things are all consequences of the fact that incandescent carbon and metals send out vast numbers of electrons. In other words, an incandescent mass of carbon is flinging negative electricity out of itself. If it is surrounded by air at ordinary pressure the effects of this are not very marked, because the presence of vast numbers of air molecules round the metal keeps the electrons from making their way very far. They must, however, exercise an immense physical effect, and the everyday phenomena of a coal fire and the combustion of carbon by oxygen is without doubt intimately connected with it. Let us see what account the electronic theory can give of such a familiar fact as the combustion of a piece of coal or carbon.

To begin the combustion, the carbon must be raised to a high temperature. As already explained, this is accompanied by a dissociation of carbon atoms. We have present in the mass of carbon not only complete carbon atoms, but free electrons or point-charges of negative electricity. Therefore there must also be the residues called "carbon positive ions," which are the result of depriving the carbon atom of one or more electrons. The carbon atom is with good reason supposed to be built up of about 12,000 electrons, and of these it can lose four negatives at most. For every four free negative electrons which have escaped, or been flung out from a carbon atom, there will be left one positive carbon ion containing 12,000 or so, *less* four negative electrons. Outside the carbon there are the atoms of oxygen and nitrogen composing the air. Various atoms can, with different degrees of facility, either lose or take up additional electrons. Electro-chemical facts indicate that the oxygen atom can acquire or take up two additional negative electrons over and above the 16,000 or so which are its normal constituent number.

Hence, we may consider that, of the electrons projected from the hot carbon, some at least find their way into oxygen atoms, giving them a negative charge of electricity and converting them into negative oxygen ions.

There will, therefore, be a strong electric attraction between the positive carbon ions near the surface of the glowing carbon, which have lost four electrons, and the negative oxygen ions hard by, which have each gained two electrons. This electric attraction will be satisfied if two oxygen ions draw near to one carbon ion and form a closely united ionic group, or carbonic dioxide molecule represented by the chemical symbol CO_2. These groups being electrically neutral, remove themselves out of the sphere of action, and are the product of combustion of the carbon. As fast as the carbon ions and free electrons are removed from the glowing carbon, fresh ones are formed to keep up the number, and so the process goes on.

The temperature of the burning carbon is kept up by the conversion of potential energy of the oxygen ions and the carbon ions into atomic kinetic energy. The electrons in each ion are set in rapid vibration, and this in turn creates waves in the æther, which are the radiated heat and light. The process is therefore continuous and self-supporting. The combination of the carbon and oxygen ions maintains that temperature which is necessary for the continual production of the electrons in the carbon, and when it is begun at one point in the mass it speedily spreads all over it.

The nitrogen atoms take little part in the process. They do not quite so easily take up electrons as do the oxygen atoms. Hence, they are not in a condition to combine with the carbon ions.

The above process is typical, and proceeds when any metal is heated in air and oxidized or burned. Returning, then, to the vacuum valve, the writer of this article has recently discovered, and announced to the Royal Society, an important property possessed by a high vacuum when the electrodes are at very different temperatures.

A glass bulb contains a carbon filament, such as would be used for an incandescent lamp, and is surrounded by a metal cylinder not touching the filament, the said cylinder being connected to a platinum wire sealed through the glass. Such an arrangement possesses the property that when the filament is rendered incandescent, negative electricity can pass from the hot carbon to the cold cylinder, but not in the opposite direction. This arrangement may act as a vacuum valve if used in the following manner: Let the filament be, for example, a 12-volt carbon filament. It must be rendered incandescent by a small insulated secondary battery, *B*. To the negative terminal of this filament is connected one end of a circuit which includes a sensitive galvanometer, *A*, and the other end of the same circuit is connected to the terminal of the metal cylinder, *C*. This circuit may include the secondary coil of a small transformer or air core induction coil, *S.P* (see Fig. 6). If, then, electric oscillations are created in the primary circuit of this transformer by the discharge of a Leyden jar or any other method, these very high frequency alternating currents produce other high frequency currents in the circuit which includes the galvanometer and the high vacuum. Only one of these sets of currents, however, can pass round the circuit, viz., that which is due to a movement of negative electricity from the hot filament to the cold cylinder. The movement of electricity in the opposite direction is prevented, hence the galvanometer gives a deflection and is traversed by a continuous current. This enables us to employ a sensitive mirror galvanometer for detecting electric oscillations.

We may modify the experiment and make use of the apparatus to show many interesting effects. We may, for instance, set up an electric oscillation by the discharge of a condenser in one circuit. This discharge produces, as is well known, a rapid alternating current dying away in intensity; the current flows first in one direction and then in the other, the interval of time between them being exceedingly small, perhaps of the order of a millionth of a second. Then at a distance several feet or several yards away, we may set up another circuit including a galvanometer and a vacuum valve, and we may produce, as above described, a deflection in the galvanometer showing it is traversed by a continuous current when we set up an alternating current in the primary circuit by the discharge of the condenser. We can then show that the high-frequency magnetic field which is producing this effect is entirely arrested by thin sheets of metal; for if we hold a sheet of tinfoil between the primary and secondary coils, the deflection of the galvanometer at once ceases. We can also make use of such an arrangement as a receiver for wireless telegraphy; it is not so sensitive, however, as the coherer or the magnetic detector, but is very useful for many purposes. It would then be used in the following way: Between the aerial wire, *A*, and the earth plate is inserted one circuit, *P*, of an oscillation transformer or induction coil, the other circuit, *S*, including a vacuum valve, *V*, and galvanometer, *G*, as already described (see Fig. 7.). If, then, electric waves from a distance fall on the aerial wire, they set up in it rapid electric oscillations, and these induce other oscillations in the circuit of the vacuum valve.

If the vacuum valve has its carbon filament ignited by a small battery, it will permit only one of the constituent currents of the electric oscillation to pass, viz., that for which the movement of negative electricity is from the hot carbon to the cool surrounding cylinder. Hence the galvanometer will give a steady deflection all the time the electric waves are falling on the wire, and if the galvanometer is that type of instrument called a "speaking galvanometer" (or one which responds very quickly to the rise and fall of current through it), it will give deflections larger or smaller in proportion as the wave trains falling upon the aerial are longer or shorter, and in this manner signals in accordance with the Morse alphabet may be transmitted and rendered visible by the deflections of the galvanometer.

A galvanometer of the above kind is used in submarine cable telegraphy, and we can employ precisely the same instrument by the aid of a vacuum valve in connection with wireless telegraphy.

These, then, are some of the practical problems to which we are led by the study of the electric conductivity of a vacuum.

UNITED STATES PATENT OFFICE.

FREDERICK SODDY, OF GLASGOW, SCOTLAND.

MEANS AND APPARATUS FOR PRODUCING HIGH VACUUMS.

No. 859,02[illegible]. Specification of Letters Patent. Patented July 9, 1907.
Application filed July 13, 1906. Serial No. 326,152.

To all whom it may concern:

Be it known that I, FREDERICK SODDY, a subject of the King of Great Britain and Ireland, residing at 46 Kersland street, Glasgow, Scotland, lecturer of chemistry in the University of Glasgow, have invented certain new and useful Improvements in Means and Apparatus for Producing High Vacua, of which the following is a specification.

The object of this invention is to obtain a high vacuum in a rapid and economical manner without the use of the mercury pump, but of a degree of rarefaction fully equal to that which can be produced by the mercury pump under the most favorable conditions.

The process employed depends on the absorption by highly heated reagents of the gases remaining after preliminary exhaustion by means of mechanical air pumps or any other means. In the prodiction of high vacua not only has the air to be removed but also the gases occluded or condensed on the walls of the vessel being exhausted and on the contained electrodes or filaments or other contents of the said vessel, which condensed gases are given up slowly after exhaustion and if not removed during the exhaustion cause the vacuum to deteriorate.

I have discovered that certain reagents, hereinafter described, will act as rapid absorbents of almost all gases when heated to a high temperature. This temperature is above that at which exhausted glass vessels soften and collapse, and as glass is the only material that can be economically and satisfactorily employed for the containing vessels in cases where the highest vacuum is desired, I have invented means for heating the reagents in exhausted vessels made entirely of glass to a higher temperature than the melting point of glass for the purpose of producing high vacua in the manner before described. Vessels of porcelain or quartz are expensive and unreliable since they are apt to become porous in use, and they cannot be joined to the vessel to be exhausted and sealed therefrom after exhaustion by means of the blowpipe in the same way as glass vessels, and metal wires for carrying an electric current cannot be sealed air tightly into any othermaterial except glass. Metal vessels cannot be employed in the production of high vacua for even if these are constructed entirely without joints or flaws of any kind, and are perfectly air-tight the gases condensed in the metal and evolved from it in vacuo prevent a high vacuum being readily obtained therein. By my invention I have overcome the difficulty of the glass vessel collapsing at the high temperature employed, and by the use of glass vessels I can produce high vacua in a practical manner by means of reagents which do not act as absorbents of gases below the softening temperature of glass.

One of the reagents I may employ is the metal calcium. I have discovered that the metal calcium under suitable conditions absorbs rapidly and completely nearly all gases, including not only oxygen and nitrogen the two chief constituents of atmospheric air but also hydrogen, carbon dioxid, carbon monoxid, water vapor, acetylene, ammonia, sulfur dioxid, and even such a complex mixture as coal gas. The aforementioned condensed gases consist chiefly of compounds of hydrogen carbon and oxygen and are readily and completely absorbed by metal calcium. But metal calcium will not entirely absorb atmospheric air, for it will not absorb the argon which is present in air to the extent of about one per cent, nor while it is in the highly heated condition will it completely retain hydrogen. The metal calcium instead of being used alone may if desired be used in the form of alloys with other metal or metals, for example with magnesium, and I include in the term metal calcium alloys containing this metal. I have also discovered that the metals barium and strontium, which are in many respects the chemical equivalents of the metal calcium, may be used instead of, but in a similar manner to metal calcium in the production of high vacua, and in the following description it is to be understood that the metals barium and strontium or alloys containing these metals as aforesaid can be employed, and all these are to be understood to be included where metal calcium is mentioned.

I have devised a method whereby metal calcium can be used in the production of high vacua, which method consists in first removing the whole of the atmospheric air from the vessel being exhausted and afterwards employing heated metal calcium, to absorb the remaining gases, including the aforesaid gases after they have been expelled from the walls, or walls and contents, of the vessel while subjected to heat. The removal of the whole of the atmospheric air may be effected by replacement of the air with such gas, or gases, as is, or are, completely absorbed by heated metal calcium, either previously to, or during preliminary exhaustion.

The heating and expelling of the condensed and occluded gases may be effected in any usual, or suitable, manner of expelling condensed and occluded gases from the walls and contents of vessels being exhausted. The usual manner of effecting such an operation is to heat the vessel while it and its contents are subjected to the same treatment as they are subjected to in after use. In incandescent electric lamps for example an electric current is passed through the filament, and in X ray bulbs an electric discharge is passed between the electrodes during the continuation of the exhaustion.

The economical and rapid production of high vacua according to my invention can be effected as follows:— In communication with the vessel to be exhausted I place a receptacle for metal calcium, the said receptacle being provided with means for heating such metal calcium sufficiently to volatilize it, in the manner hereinafter to be described, means being also provided for placing the said vessel and receptacle in communication with a mechanical, or other, exhauster, and with a receptacle containing a substance which will generate gas capable of being entirely absorbed by heated metal calcium, and I first put the exhauster in communication with the vessel and receptacles and exhaust, as far as is possible by this means, air from the vessel and receptacles, and then I shut off the exhauster and generate the gas capable of being entirely absorbed by heated metal calcium as aforesaid, and I again exhaust by means of the exhauster, repeating this supply of such gas and exhaustion as may be necessary to replace and remove all the air, and consequently all the argon. I then shut off the vessel being exhausted and the receptacle containing the metal calcium from the exhauster and the receptacle containing the gas generating substance and keep the vessel and its contents heated and subjected to such treatment as hereinbefore indicated as will expel all condensed, and occluded, gases from the walls and contents of the said vessel, and I heat to the temperature at which it commences to volatilise the metal calcium which then absorbs all remaining gases and also the gases expelled as aforesaid. Instead of using a special substance to generate a gas, as aforesaid, for use in removing the air remaining after the preliminary exhaustion, the preliminary exhaustion may be continued while the vessel and its contents are subjected to such treatment as hereinbefore indicated as will expel the condensed and occluded gases, and the gases expelled from the vessels and contents of the said vessel be utilized instead of gases generated from a special substance as aforesaid, this being possible, for instance in the case of vessels and contents not previously exhausted.

Commercial samples of metal calcium give off gases, consisting mainly of hydrogen, carbon, and oxygen, when heated in a vacuum to a temperature below that at which these gases are absorbed by metal calcium, but these gases are reabsorbed on raising the temperature of the metal calcium. Use may be made of the gases evolved from metal calcium, in this way to assist in the replacement of the air remaining in the apparatus in the manner before described. This is possible in the case of a new charge of calcium not previously heated in a vacuum.

When the metal calcium has absorbed the remainder of the gases which have been expelled, the exhausted vessel may be sealed off and a very high and permanent vacuum has been obtained in a rapid and economical manner. Towards the end of the process of absorption of the gases by the metal calcium the temperature of the metal calcium can, with advantage, be reduced, for I have found that certain of the compounds formed by the combination of metal calcium with the gases it absorbs (and particularly the compounds with hydrogen and with carbon) possess an appreciable tension of dissociation at high temperature, but that on sufficiently lowering the temperature the gaseous products of dissociation are completely reabsorbed by the metal calcium, and the vacuum resulting is improved.

Figure 1 of the accompanying drawings illustrates diagrammatically means I may employ in carrying out the process according to my invention. A is the vessel to be exhausted, for example, an X ray bulb, B is the receptacle in which is [illegible] container of the metal calcium C, means being provided as at c, for heating it electrically to a high temperature as hereinafter described. D is the receptacle containing a substance which will furnish gas, or gases, capable of being entirely absorbed by metal calcium. This receptacle D may be, for example, a glass tube containing a mixture of, say, potassium chlorate and manganese dioxid furnishing oxygen on warming. E is the glass tube connected to the exhauster, not shown. F is a tap to open and close communication with the exhauster, and G is a tap to open and close communication with the receptacle D. H is a spectrum tube which may be of the usual kind and is a convenience for determining by means of the spectroscope the nature of the residual gases in the vessel undergoing exhaustion.

I will now describe constructions of apparatus suitable for use in carrying out that part of my invention which relates to the heating of the reagent to a high temperature in a glass containing vessel, for the purpose of causing it to absorb the remaining gases and so produce a high vacuum. For this purpose I employ, in combination with electrical means, as hereinafter described, for supplying heat to the reagent within the glass vessel, means for protecting the walls of the glass vessel from softening, or melting.

As the glass vessel is partially, or completely, exhausted, the conduction of heat from within outward to the walls is much diminished and in some cases I also interpose a shield, or shields, of refractory material between the reagent being heated in the said vessel and the walls of the said vessel to intercept heat radiated. The electrical heating is obtained by conduction of an electric current through a separate resistance circuit placed within the said exhausted glass vessel, or by electrical means situated outside the said glass vessel and causing induced electrical effect through the walls of the said glass vessel, either in a circuit composed of the reagent to be heated or in a separate circuit within the said exhausted glass vessel in close proximity to the reagent. For example, in one modification of my apparatus I employ a combination of an exhausted glass vessel with an electrical resistance circuit within the said glass vessel and surrounding the reagent to be heated and a shield, or shields, of refractory material placed between the said resistance circuit and the walls of the glass vessel, and in another modification I employ a combination of an exhausted glass vessel with a core of iron wires, or strips, inside the said vessel, and I dispose around the outside of the vessel a coil traversed by an alternating, or intermittent, current of high periodicity, and I place around the core a ring, or tube, composed of a good conductor of electricity in which the heating current is induced. This ring, or tube, may, in some cases for example in the case of metal calcium, be made of the reagent to be heated, or of a separate substance on, or in, which the reagent to be heated is placed. In addition I may use with this combination a shield, or shields, of refractory material which, in this case, must be an insulator of electricity, between the substance heated and the walls of the glass vessel, and also I may use a shield between the substance heated and the iron core. When the heating current is induced directly in the substance to be heated, this substance is hotter than its surroundings, so that less heat is required than for any other mode of heating and the glass vessel needs less protection in this case and the shield, or shields, of refractory material may, in certain cases, be dispensed with.

Figs. 2 to 5 represent a form of the apparatus according to the first mentioned modification, Figs. 3, 4, and 5 being respectively sections on the lines *x*, *y* and *z*, Fig. 2. Figs. 6 and 7 show a form of the apparatus according to the second mentioned modification. Figs. 8 to 12 represent another modification as hereinafter described.

Referring first to Figs. 2 to 5. The glass vessel B is closed by a glass tube B^2 ground into the vessel B, and having two hollow legs, or pockets, *b*, filled with mercury into which penetrate the platinum conductors b^2 from the respective poles of any suitable source of electricity. I is a porcelain insulator through longitudinal holes in which pass the conductors *i i*, the lower ends of which dip into the mercury in the legs, or pockets, *b* and passing within the porcelain tube J and out through holes *j j* therein, and to the said conductors is joined an electrical resistance wire i^2 (of platinum, or other suitable material,) coiled round a helical groove on the porcelain tube J which is surrounded by a porcelain shield-tube K. Inside the tube J is carried the porcelain container L for the reagent C, which is to be heated. The upper enlarged part is employed when a reagent such as metal calcium is used which gives off a vapor which it is desirable to condense this enlarged part constituting a surface upon which the vaporized reagent will deposit. The shield-tube K serves to protect the glass of the vessel B from the heat radiated from the resistance wire i^2. If desired there may be more than one shield-tube of refractory and insulating material between the substance to be heated and the glass vessel B, or the glass vessel may be formed into a bulb at the part where the greatest heat is developed.

Referring to the modification shown in Figs. 6 and 7, this shows an arrangement adapted for use when the reagent, for example, metal calcium, is itself a conductor of electricity and can be made into suitable form. The substance to be heated is made into the form of a ring, or tube, C which may be supported in a tube K constituting a shield of refractory and insulating material, in the glass vessel B. Within the substance C and this tube K are iron wires, or strips, M arranged after the manner of the core of an induction coil and contained in the tube P of thin glass, or porcelain. The ring, or tube, C is heated by an electric current induced in it either by a bobbin of insulated wire, or by spiral strips, as shown at N, traversed by an alternating, or intermittent, current of high periodicity and coiled outside the glass vessel B and therefore surrounding the iron core within it. This heating arrangement constitutes an alternate, or intermittent, current transformer of which the outside coilings N constitute the primary, the ring, or tube, C the single short-circuited winding of the secondary, and the iron wires, or strips, M the core. It may be convenient to obtain the alternating, or intermittent, current from a step-down transformer (not shown) of which N is the secondary and C is the tertiary. If necessary, in this case also, more than one shield K, may be used, or the shield K, (or shields), may, in some cases, be dispensed with as explained, and the outer glass tube at this part be expanded into a bulb, and the core M be made longer and the spiral N be placed above, or below, the bulb. The ring C in this case is conveniently supported on a projection on the tube K. When it is desirable to protect or inclose the core M the said core may, as shown, be contained in a sealed tube P of difficultly fusible glass, which, if necessary, may be protected externally by wrapping round it a sheet of mica, or other refractory material, or by placing round it a concentric shield of porcelain. With this method of heating, the limitation of temperature is fixed mainly by the loss of the magnetic properties of the iron core above a certain temperature, so that for very high temperatures the iron as well as the glass walls must be shielded. For the purpose of charging and cleaning the apparatus, the glass vessel B may, if desired, be made in two, or more, parts ground to fit together accurately without leakage when the ground joint is lubricated with rubber grease in the usual manner.

Fig. 8 represents a ½ scale modification of the apparatus for use in the inductive method of heating upon the same principle as that last described. Fig. 9 is a section actual size of a part of the apparatus. Fig. 10 is a central transverse section; Fig. 11 a section at right angles thereto and Fig. 12 a horizontal section. The reagent, for example, metal calcium, is in the form of a disk C with a central hole through which a magnetic material such as a bundle of iron wires, or strips, M, passes the said wires, or strips, supporting the disk C, centrally, in the glass vessel B. Outside the glass vessel B is a magnetic material such as a bundle of iron wires, or strips, M^3, bent into approximately ring form and so arranged that it forms, with the iron wires, or strips, M, or the equivalent, inside the glass vessel B a magnetic circuit with two air gaps in which part of the walls of the glass vessel B are situated. A conductor N, of copper, or other suitable metal, is coiled around the outer wires, or strips, M^3, and through this is passed a rapidly alternating, or intermittent, electric current so as to induce a magnetic flux in the magnetic ring and consequently in the bundle of wires, or strips, M, or the equivalent, within the glass vessel B, and so heat the disk C. The disk C may if desired be made of a good conductor, for example, copper, and the reagent heated in a cavity in the same. Or, two disks of copper and a disk of the reagent placed between the other two disks may be employed. The drawing shows two caps, or shields, P^2 of porcelain, or other sufficiently refractory material which is a bad conductor of heat, these caps, or shields, being used to protect the walls of the glass vessel B from the heat generated in the disk C.

Having now particularly described and ascertained the nature of my said invention and in what manner the same is to be performed, I declare that what I claim is:—

1. The process of producing high vacuum which consists in bringing a heated alkaline earth metal capable of absorbing gas into the presence of a rarefied atmosphere whereby the remaining gases are absorbed.

2. The process of producing high vacuum which consists in subjecting a vessel to preliminary exhaustion, expelling the condensed and occluded gases from the walls of the vessel and bringing said gases into the presence of a heated alkaline earth metal capable of absorbing gas.

3. The process of producing high vacuum which consists in subjecting a vessel to preliminary exhaustion, expelling the condensed and occluded gases from the walls and contents of the vessel, and bringing said gases into the presence of a heated alkaline earth metal capable of absorbing gas.

4. The process of producing high vacuum which consists in subjecting a vessel to preliminary exhaustion, expelling the condensed and occluded gases from the walls of said vessel, bringing said gases into the presence of a heated alkaline earth metal capable of absorbing gas and permitting said metal to cool, substantially as described.

5. Apparatus for the purpose of producing high vacuum by heating in an exhausted glass vessel to a temperature above the softening point of glass any reagent which becomes an absorbent of gases at high temperature, the said apparatus consisting of the combination of a glass vessel adapted to be exhausted, means for supporting therein the reagent and means for electrically heating such reagent within the vacuum and means for preventing the intense hea. being conveyed to th walls of the said glass vessel, substantially as hereinbefore described.

6. Apparatus for the purpose of producing high vacuum by heating in an exhausted glass vessel to a temperature above the softening point of glass any reagent which becomes an absorbent of gases at high temperature, the said apparatus consisting of the combination of a glass vessel adapted to be exhausted, means for supporting therein the reagent to be heated and means for heating such reagent within the vacuum by means of an electric current passing through a conductor external to the glass vessel and inductively heating the aforesaid reagent by current, and means for preventing the intense heat being conveyed to the walls of the glass vessel, substantially as hereinbefore described.

In testimony whereof I have signed this specification in the presence of two subscribing witnesses.

DEFENDANT'S EXHIBIT No. 18.

surveyors and astronomers. The examples are mostly taken from actual observations, and the necessary calculations are given in considerable detail. In the earlier chapters a knowledge of determinants is not assumed, and the explanations given ought to make the method intelligible to readers of quite moderate mathematical ability. For the more difficult and controversial points of the theory, reference is made to the treatise of Czuber; at the same time, a very good example of the unavoidably empirical nature of the whole subject is given by working out the same elementary problem according to each of three different laws of error. Now that the measurements of physics and chemistry are approaching, not to say surpassing, in exactness those of astronomy and geodesy, a practical work of this kind is likely to assist a larger and larger body of experimenters.

Die Purpurbakterien. Eine mikrobiologische Studie. By Prof. Hans Molisch. Pp. 92. (Jena: Gustav Fischer, 1907.) Price 5 marks.

THIS memoir deals with an interesting group of chromogenic microorganisms, *viz.* those producing brilliant pigments ranging in tint from pink, through rose and deep red to reddish-purple. They are probably more nearly allied to the coloured algæ (Phycochromaceæ) than to the bacteria proper, and one of the earliest descriptions of a member of the group was given by Sir Ray Lankester in 1873 under the title of a "peach-coloured bacterium." The author first discusses the occurrence in nature of these organisms. Sometimes they are met with in great abundance on the sea-coast, in river estuaries, and in hot and sulphur springs. Directions are given for obtaining growths in various organic mixtures, for the preparation of suitable culture media, and for obtaining pure cultures in the latter. The biological and physiological properties are next considered; while light has an inhibitory, or a germicidal, action on most bacteria, the "purple" bacteria develop best in its presence. They are sensitive to all light rays, but in particular to the ultra-violet ones; they do not, however, evolve oxygen in the presence of light, and their need for oxygen varies much, some species being almost anaërobic.

The colouring matter produced by the "purple" bacteria is a mixture of two pigments—a green, "bacteriochlorin," and a red, "bacteriopurpurin." The chemical and other properties of these are described fully.

As regards classification, the organisms are grouped in a special order, the Rhodobacteria. This is divided into two families, distinguished by the presence or absence of sulphur granules, and several new species isolated by the author are described. Altogether the book forms a very useful summary of our knowledge of an interesting and peculiar group of micro-organisms.

R. T. HEWLETT.

The Case of Existence. By Norman Alliston. Pp. xiii+262. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1907.) Price 5s. net.

"OF the enigmas of life," says Mr. Alliston in his introduction, "all speak; but nobody acts as if there were an enigma." It is his object to remove this inconsistency by exposing the confusions of thought of those who "want life speculatively to be a mystery." The book has three parts. The first contains a good account of the nature of Explanation and some not ineffective criticisms of Knowledge, Nature, &c., mingled, it must be admitted, with much rather ill-informed dogmatism. The second, in the course of a review of man's "obstinate questionings" about existence, develops the author's peculiar egoistic optimism. The third, in which he draws his ethical corollaries, unfortunately contains some chapters which many readers will find offensive both in matter and in tone. The book contains little to engage the attention of the practical student of philosophy, but, being written with obvious conviction and enthusiasm, may here and there attract a useful recruit to the study of first principles. At a later stage the student may not unprofitably return to these pages to detect and analyse the crudities and ambiguities which abound under a surface of apparent lucidity.

Science German Course. By C. W. P. Moffatt. Pp. xii+228. (London: W. B. Clive.) Price 3s. 6d.

THE portion of this book devoted to grammatical construction and word formation occupies about eighty pages, and is followed by extracts for translation from the German. These selections deal with various scientific subjects, and can be commenced after the student has made himself familiar with the first few pages of the grammar that precedes them. Short vocabularies are given of technical terms in mathematics, physics, chemistry, geology, botany, and zoology. The book thus provides a convenient means of obtaining sufficient acquaintance with the German language to read simply scientific descriptions in it with intelligence.

The Wehnelt Kathode in a High Vacuum.

THAT a good vacuum can be made into a good conductor by the use of an incandescent kathode is known since the discovery of the Edison effect, and has been investigated with great thoroughness by O. W. Richardson (Trans. Roy. Soc., 1903, 201 A, 497). Wehnelt has shown (*Ann. d. Physik*, 1904, iv., 14, 425) that if the incandescent kathode is coated with one of the alkaline earths, surprising results can be obtained. From a platinum foil kathode at 1300° C. to 1400° C. coated with lime, two to three amperes per sq. cm. of surface can be passed through a good vacuum, the kathode fall being practically negligible, and the total voltage across the vacuum tube being below 30 volts. This result is so very remarkable that I have repeated it in the following way to test whether, as is commonly supposed, the phenomenon is really independent of the perfection of the vacuum.

In a tube provided with a Wehnelt kathode of about 2 sq. cm. area was mounted an anode of the metal calcium. I have recently shown (Proc. Roy. Soc., 1907, 78 A, 429) that calcium at its volatilising temperature (700° C. to 800° C.) absorbs practically instantaneously and very perfectly all known gases and vapours except the chemically inert gases of the argon family, and have described a form of vacuum furnace suitable for this operation. The tube was prepared in the usual way by preliminary exhaustion and washing out with oxygen to remove argon, and then subjected to the action of calcium heated in a furnace attached to the apparatus. When a good vacuum had been obtained, current from the 250-volt supply was passed through the tube between the heated Wehnelt kathode and the calcium anode in order to heat the latter.

The gases evolved from the anode and tube under this treatment were absorbed by the calcium in the furnace. The current was regulated by a resistance to about 1·2 amperes, and was interrupted at intervals to give the evolved gases time to flow out of the apparatus. When the gases had been for the most part removed the current was passed continuously, heating the calcium anode up to its volatilising point. Quite suddenly and completely the current through the tube stopped, and at the same moment a copious mirror of calcium was volatilised from the anode. In a little while a very feeble glow started and passed intermittently from time to time, but it was not enough to move the ammeter needle, and was most likely due to a further slow evolution of gas from the still heated surfaces. A current could be passed by a coil from the hot kathode to a third electrode as anode without causing any appreciable resumption of the flow in the 230-volt circuit.

More gas was then generated within the apparatus by heating the third electrode with the coil discharge, and the current in the main circuit resumed its original intensity, again heating up the calcium anode. The original phenomenon was repeated, a sudden cessation of current taking place when the calcium volatilised. Just before stopping, the glow of the tube changed to that characteristic of argon, so probably a trace of air had not been removed. The whole phenomenon could be repeated by admitting oxygen to the apparatus and proceeding as before.

This experiment shows that in a sufficiently high vacuum the Wehnelt electrode ceases to be effective. In the experiments so far recorded the saturation current has increased with the improvement of the vacuum, and the phenomenon has been supposed to be in the first place independent of the residual trace of gas present. Wehnelt (*loc. cit.*, p. 446) remarks:—"Für Drucke unter 0·1 mm. ist die für eine bestimmte Temperatur ausgesandte Zahl von negativen Ionen unabhängig vom Druck," and (p. 456) "die Grenzstromstärken um so höher sein . . . je tiefer die Druck ist." In his description of his modification of the Braun tube (*Phys. Zeit.*, 1905, vi., 732) he says the vacuum in the tube must be as perfect as possible.

Richardson, whose mathematical theory of the general phenomenon has received quantitative experimental confirmation, and has been accepted by Wehnelt in the case of his electrode, regarded the action as purely electronic. Commenting on the magnitude of the current and the smallness of the residual gas—in one experiment 2 amperes per sq. cm. at a measured pressure of 0·0016 mm. from a carbon lamp-filament—he says (*loc. cit.*, p. 546):—"This (the current) is twenty-five times the maximum value obtained by supposing each molecule to produce one ion; so that it is highly improbable that any considerable part of the conductivity investigated is due to ions produced in this way. . . . Both these points of view lead to the conclusion that the corpuscles are not produced by a dynamical action between the molecules of the surrounding gas and the surface of the metal. In fact, all the experimental results seem to point to the view that the corpuscles are produced from the metal by a process similar to evaporation."

These isolated quotations, of course, may not fairly express the opinions of the authors about what is a very complex phenomenon; but the general impression their results has conveyed, I think, has been that the large currents dealt with were wholly conveyed by the expelled electrons, and therefore should pass through any vacuum, however perfect. I do not think the electronic emission can account for more than a negligible fraction of the total current, which is carried almost wholly by the residual gas.

The results here given bear out the general view I have from time to time advocated since my experience with the use of calcium, that degrees of vacuum are in practice apt to be overrated, and really high degrees of vacuum are not so readily obtained as is commonly supposed.

The Interpretation of Mendelian Phenomena.

I am strongly inclined to agree with Dr. Archdall Reid that Mendelian investigations throw no light on many of the most important problems of biology, such as the causes of variation, the evolution of adaptations, and many others. On the other hand, it is difficult to understand what Dr. Archdall Reid means by the statement that Mendelism is the investigation of sex. In one of his letters he describes Mendelian phenomena as "abnormalities of sexual reproduction which occur under conditions of artificial selection." If this means peculiarities of heredity in sexual reproduction observed in cultivated varieties, it may be allowed to pass; but in an appendix to the second edition of his "Principles of Heredity," Dr. Reid states that the inheritance of Mendelian characters is probably sexual. He proceeds as follows:—"Nature has evolved alternative inheritance to create and perpetuate sexual differentiation, but, just as blending of sexual characters sometimes occurs, so on the other hand the inheritance of non-sexual characters is sometimes alternative. As we have seen, whenever the latter happens, the non-sexual differences are, like the sexual differences, usually considerable. Nature makes the mistake, so to speak, of treating them as sexual. Of course, however, the alternative inheritance of large non-sexual differences is not certain, not so 'clean' as that of sexual differences, the alternative inheritance of which has been established by a long course of selection."

According to this, the alternative inheritance of non-sexual characters is of the same nature as sexual dimorphism. It seems to me that Dr. Reid has not sufficiently studied the inheritance of secondary sexual characters. It is admitted by almost all evolutionists from Darwin himself downwards that selection cannot have been the cause of the alternative inheritance of sexual differences. The female in selecting a particular male cannot prevent the transmission of his peculiarities to her daughters. The male characters must be limited to the male sex from their first origin as variations, because otherwise the selection of the individual male would merely ensure their transmission to both sexes.

The essential peculiarity of secondary sexual characters is their physiological connection with the primary, *i.e.* with the male or female gonads. It is not merely a question of alternative inheritance; both male and female characters are inherited by each individual, but normally only one set is developed. When, however, the male gonads are removed, the male characters are usually not normally developed, but suppressed. In Mendelian cases the development of alternative characters is usually entirely independent, both in theory and fact, of the sex or condition of the gonads.

The contrast of male and female corresponds to alternative dominance in a heterozygote; male characters are dominant in male, female in female, but either can and does transmit both. In Mendelian cases alternative inheritance is segregative; a recessive transmits only recessive characters, a pure dominant only the dominant. In other passages which I could quote Dr. Reid has shown that he has failed to appreciate this fundamental distinction between dominance and segregation, between the heterozygote and the homozygote, between the first generation of a Mendelian cross and the second.

Excepting parthenogenesis, the heredity of all characters is sexual in that it is connected with fertilisation, but I do not see that Mendelian characters are sexual in any other sense. The theory that the inheritance of sexual characters is Mendelian is one which has a definite meaning and can be investigated. Dr. Archdall Reid's statement that Mendelian inheritance is sexual is in one sense a truism, in another seems to me to have no real meaning at all, for to say that nature has evolved alternative inheritance to perpetuate sexual differentiation explains nothing.

J. T. Cunningham.

Highgate, November 3.

I am very willing, and, like most people with theories, I believe I am able to maintain the correctness of the views to which Mr. Cunningham refers; but to discuss my speculations now would be to confuse the issue. I may say, however, that the appendix to the second edition of my work, from which Mr. Cunningham quotes, is a mere sketch hastily thrown together to meet the objections of critics who had advised the lay and scientific public that a book, which I fondly hoped contained a little that was new, and which certainly contained more than a little of which Mendelians seem profoundly unaware, was antiquated and worthless, not because there were no new facts or inferences in it, nor because its facts and inferences were invalid, but simply and solely because I had not adopted "the new method" nor accepted the

I.—*Introductory.*

This paper contains an account of researches carried out by the aid of an electric furnace designed to heat reagents in soft glass tubes up to temperatures far above the softening point of glass, and has special reference to the use of calcium under these conditions as a valuable absorbent of gases. Recent work on the generation of helium from the radio-elements has shown the necessity for more simple, certain, and powerful means of absorbing other gases and in particular nitrogen. The usual practice of Sir W. Ramsay and the writer when working together was to make provision for the removal of compounds of hydrogen, oxygen, and carbon, but to take the utmost precautions against the admission of air into the apparatus in the first place. If nitrogen was present in spite of the precautions taken, it was often possible, by gently running the spectrum-tube, to absorb it by the hot electrodes of aluminium, the lines of helium, if present, appearing as the nitrogen spectrum faded.

The difficulty in absorbing nitrogen is that the usual absorbents, for example, a mixture of lime and magnesium, only react above the softening temperature of an exhausted soft glass tube, and the present researches had their origin in an attempt to enable higher temperatures and more powerful absorbents of gases to be used within soft glass apparatus. Lithium, it is true, absorbs nitrogen at a very low temperature, but its use introduces hydrogen. A good example of a very perfect train of absorbents, able to absorb all known gases with the exception of those of the argon family, is to be found in the recent researches of Debierne* on the production of helium from radium and actinium. "Oxygen is absorbed by heated copper; the absorption of hydrogen is secured by the action of heated copper oxide and phosphorus pentoxide, at the same time the copper oxide transforms gaseous carbon compounds into carbon dioxide, which is absorbed by potash, and finally nitrogen is absorbed by pure lithium."

Now such an apparatus serves but one experiment, and has to be built up afresh for each, because it is necessary to fill it after the absorption with mercury in order to compress the helium sufficiently to detect it. The labour involved during a lengthy investigation may be imagined. It is, therefore, very satisfactory to be able to state that I have found that a single reagent, namely, calcium, at the high temperature attainable by the use of my furnace, would serve instead of all the reagents employed by Debierne, and do the work far more effectively and rapidly. Calcium, under the conditions mentioned, is a universal absorbent of all gases with the exception of the argon group.

II.—*Historical.*

Till recently calcium has been a very uncommon metal, while barium and strontium still belong to the category of chemical curiosities. Maquenne† found that when amalgams of these three metals were heated in nitrogen, the mercury was volatilised and nitrides of the metals were formed. The absorption took place at a lower temperature than in the case of the metals magnesium and aluminium. Barium was stated to lend itself best to the experiment. None of the alkaline-earth metals were investigated by Lord Rayleigh and Sir W. Ramsay in their examination of the known absorbents of nitrogen,* on account of the difficulties in obtaining large quantities of these metals at that time. After the discovery of argon, Maquenne† showed that a mixture of calcium oxide and magnesium rapidly absorbed the oxygen and nitrogen of the air when heated in a hard glass tube, and attributed this reaction to the production of calcium in an extremely divided state. He states that a manometer attached to the apparatus showed a diminution of pressure from the atmospheric equal to 70 and even 73 cm. of mercury. This mixture is now commonly employed in the preparation of argon, and it is customary to accept Maquenne's explanation of its absorbing power. It is, however, quite certain that the commercial calcium in the form of compact metal bars, produced by electrolysis, behaves in a manner entirely different from the "nascent calcium," if such it be, produced by heating a magnesium and lime mixture, for the former, heated in a tube filled with air at atmospheric pressure, produces no noticeable absorption, even at the highest temperatures.

---

* 'Comptes Rendus,' 1905, vol. 141, p. 383.

† 'Comptes Rendus,' 1892, vol. 114, p. 220.

Moissan first succeeded in preparing calcium in quantity sufficient to make an accurate study of its properties.‡ His calcium was in finely divided crystalline condition, and was obtained by acting upon calcium iodide with excess of sodium. The calcium is deposited out from the sodium on solidification, and the latter is removed by the action of absolute alcohol, which does not attack calcium. He showed that at a dull red heat this calcium absorbs both hydrogen and nitrogen with incandescence, forming nitride and hydride respectively. The hydride heated to the softening temperature of a Bohemian glass tube in an atmosphere of hydrogen neither absorbed nor evolved gas. In a determination of its melting point the calcium was heated in a vacuum obtained by the use of a mercury pump. Moissan noted the evolution of small quantities of gas which were pumped off, "but as soon as the metal became dull red hot the last traces of gas are absorbed, and the vacuum stood at 1 mm." This inconsistency might have been due to sticktion of the mercury in the gauge, or to an error in its reading, for, as Moissan himself remarks, the last traces of gas are absorbed under these conditions.

---

* 'Phil. Trans.,' A, 1895, vol. 186, p. 187.

† 'Comptes Rendus,' 1895, vol. 121, p. 1147.

‡ 'Comptes Rendus,' 1898, vol. 126, p. 1753; and vol. 127, pp. 29, 497, and 584.

Calcium, electrolytically produced in the form of compact bars, free from mercury and oil, has been available for over two years, and has been the subject of much interest. Those who have examined it must have been more struck with its apparent disinclination to react than with any exceptional reactivity. Thus the attempts to replace the magnesium or magnesium-lime mixture by this calcium in the preparation of argon have never succeeded in my experience. Even when heated to 1200° C. in an electric oven it refuses, after a very slight initial action, to absorb nitrogen. It must be heated to a very high temperature in the blow-pipe before it ignites in the air, and then readily goes out. In one experiment a powerful arc was caused to pass between calcium points in air without inducing combustion.* Negative results of this character could be multiplied.

Arndt† undertook a research on the melting point of commercial calcium, in which the metal was heated, as in Moissan's experiment, in a vacuum of 1 mm. pressure to avoid chemical action. He noticed that the calcium began to volatilise below its melting point, and that the vapour reacted energetically with the residual air, so that the pressure on the manometer sank to an unreadable value. Absorption commenced at 700° C., was rapid and accompanied by visible volatilisation at 730°, whereas the melting point was found to be 800°. When a Plücker spectrum-tube was included, it was found that "the nitrogen spectrum faded rapidly, while the lines of hydrogen (from a trace of water present) remained behind with the lines of argon." He found that the vapour of magnesium did not exhibit nearly the absorptive power of calcium.

With the use of the apparatus to be described I arrived independently at and have confirmed, the observation of Arndt on the extreme rapidity of absorption of the oxygen and nitrogen of air by the vapour of calcium. In addition I have found that all the common gases can be absorbed equally well, although in some cases, as the above quotation from Arndt's paper shows for hydrogen, complete absorption is not effected by simple heating alone.

III.—*Electric Furnace for Strongly Heating Reagents in Glass Vessels.*

The apparatus usually employed depends upon the internal heating of the reagent by an electric resistance circuit and the protection of the glass walls by a screen of porcelain placed between it and the enclosed furnace. It is shown to the scale of 6 inches to the foot, in section, in fig. 1. Figs. 2, 3, 4 are transverse sections on the lines *x*, *y*, *z* respectively. The outer containing

---

* This, however, is partly due to the extraordinarily slight heating which electrodes of calcium experience when a discharge is passed through a gas between them. Of all metals calcium heats the least, and is in this respect far superior to aluminium. But for other difficulties it might be used to replace aluminium, with advantage, as the electrodes of vacuum tubes in the case of the inert gases. A steady arc can be maintained between calcium points in air with a very small amperage.

† 'Ber. d. D. Chem. Ges.,' 1904, vol. 37, p. 4723.

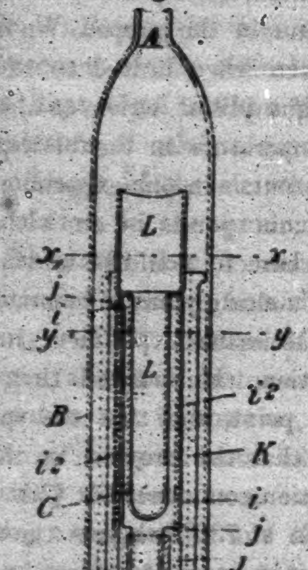

Fig. 2

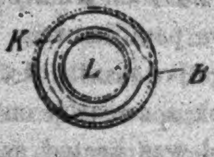

Fig. 3.

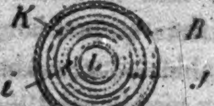

Fig. 4.

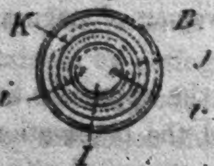

Fig. 5.

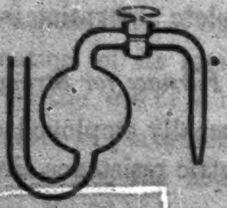

vessel is made out of soft glass tubing, and is in two parts, the upper *B* and the lower B_2, which are ground to fit together accurately at *D*. The lower part B_2 has two mercury cups with platinum wires b_2 sealed through the glass. The upper part *B* widens at the shoulder *d*, on which rests the porcelain shield-tube *K*. This is slipped into the tube, which is then constricted at *A* and joined to a narrow piece of tubing for connecting to other apparatus. The furnace-tube *J*, which carries the heating wire, slides through the ground-joint of *B* and passes inside the shield-tube *K*. For the upper part of its length it is grooved with an external screw thread of about 1 mm. pitch, and wound with a platinum wire *ii* of 0·25 mm. diameter. It passes through the holes *jj* into the inside of the tube, and is joined to stouter leads of nickel, copper, or platinum, or is simply doubled on itself. The leads pass through the doubly-bored porcelain insulator *I*, which slips within the lower half of the furnace tube and the upper part of B_2, and are finally taken into the mercury cups. The lower end of the furnace-tube *J* rests on, and is supported by, the upper end of B_2, and itself surrounds and supports at its upper end a porcelain test-tube *L*, in which the reagent to be heated is placed, at *C*.

The whole arrangement is readily taken to pieces at the ground-joint *D* for recharging, cleaning, or repairs. The end B_2 usually carries between the two mercury cups a narrow tube, shown by dotted lines, to which is attached a bulb and tap, shown in fig. 5, for the purpose of admitting mercury into the apparatus without introducing air, and also for conveniently filling the mercury cups and other purposes. An oil or mercury seal may surround the ground-joint, but is not necessary if it is of good workmanship.

For special work, where the possibility of leaks or the presence of vapour of grease is to be avoided, it is easy to dispense with the ground-joint *D* and to make the apparatus in one piece. In this case *B* is made long, so that it can be repeatedly opened and sealed, and the various parts are introduced through the upper end by suitable tongs. But these refinements are usually quite unnecessary if the ground-joint is of good workmanship, and is well lubricated, and if the leads are of sufficient conductivity not to heat the joint. In special work, too, the mercury cups may be dispensed with and the wires continued through the glass seal if the presence of mercury vapour is to be avoided.

[*Added*.—An improved and thoroughly satisfactory method of working, applicable whether the ground-joint is used or not, is to dispense with the porcelain insulator *I*, and to bore two holes opposite each other at the lower end of the furnace-tube *J*, twisting one end of the doubled platinum heating wire through each hole, together with a length of "flexible" copper wire, and continuing the two flexibles, insulated if necessary in little glass tubes, into the cups *bb*, where they make good touching contact with the platinum, without the use of mercury. In this way a mechanically strong joint with the fine heating wire is secured, the presence of mercury inside the vacuum is altogether avoided, and the formation prevented of a mercury arc between the two cups when a high-tension discharge is passed through the vacuum, which in the first form of apparatus constituted an occasional source of annoyance and damage.]

With this apparatus reagents may be safely heated to temperatures far above the melting point of glass without injuring the apparatus. After nearly two years' use of these furnaces I do not recall a single case where the heat has caused the glass to crack or break while in use, although, of course, the glass tends to get brittle and to break when being cleaned more readily after use than before. If required for prolonged heating at high temperature, it is an advantage to blow a bulb on the tube at the hottest part of the furnace, otherwise, when the porcelain shield-tube has become heated through, the glass is apt to melt. These shield-tubes never break. The furnace-tubes are more fragile, but stand extremely well, while, of course, the test-tubes containing the reagents require the most frequent replacement. Tubes made of thin iron would for many purposes have very many advantages over porcelain. But they must be gas-tight at the lower end, for the vapour of calcium would ruin the platinum wire if it came in contact with it.

The limit of temperature attainable in this apparatus is fixed mainly by the volatility of the heating wire in the high vacuum usually maintained within the apparatus, and for this reason platinum or one of its alloys must be used. Iron or nickel volatilise and the wire is destroyed in a few minutes. Even with platinum the volatilisation of the metal is serious at a bright-red heat. In addition, a certain tendency to become brittle with loss of metallic qualities, which is noticeable in ordinary platinum resistance furnaces, thermometers, and thermocouples, and which prevents their prolonged use at temperatures above 1200° C., appears to be far more marked and to take place at lower temperatures in the high vacuum, rendering occasional rewindings of the furnace necessary. The cause of this has not been fully explained. An examination of somewhat analogous phenomena in the case of nickel has been recently made by Dr. H. C. H. Carpenter in a paper read before Section G of the British Association this year, and attributed by him to gases in the nickel.* I am inclined to connect the phenomenon in the case of platinum with the vaporisation of the metal. If tantalum wire could be obtained, no doubt it would prove far more suitable than platinum. Naturally, a high vacuum within the apparatus tends greatly to conserve the heat and to diminish convection, and the risk of the outer vessel melting. In this respect the apparatus is the antithesis of the Dewar vessel for storing liquid air.

* 'Engineering,' August 17, 1906, p. 222.

IV.—*Absorption of Gases by Calcium.*

If the apparatus described, charged with a small piece of calcium, and furnished with a Plücker spectrum-tube, is exhausted by a Fleuss pump, and the furnace heated, gases, consisting of compounds of hydrogen, carbon, and oxygen are given out by the calcium. If connection with the pump is then shut off and the heating continued, absorption of the remaining gases, accompanied by volatilisation of the calcium, takes place, and the vacuum rises almost instantly to a point at which no discharge can be passed through the spectrum-tube. By a non-conducting vacuum is to be understood one of greater resistance than an alternative spark gap in air of 2 to 3 cm., unless the length of the gap is given.

If air is introduced into the apparatus, all but argon is rapidly absorbed, and quantities up to 10 or 20 c.c. can be thus dealt with. These experiments with air are, however, of interest from so many points of view that they will be dealt with in detail later.

In a similar way it was shown that carbon monoxide, carbon dioxide, water vapour, hydrogen, acetylene, sulphur dioxide, ammonia, and the oxides of nitrogen (nitric oxide, with deflagration of the calcium) are all as readily and completely absorbed as in the case of the oxygen and nitrogen of the air. Quantities of several cubic centimetres disappear within a minute after introduction, and the vacuum-tube becomes non-conducting.

Finally, in order to put the power of the calcium to as severe a test as possible, several successive quantities of coal gas, each of several cubic centimetres, were introduced into the apparatus after the absorption temperature had been attained. Within a minute after each addition the spectrum-tube became non-conducting to the discharge. Calcium thus acts as a universal absorber of chemically valent gases.

The case of hydrogen and its compounds alone calls for fuller treatment, for at too high temperature calcium hydride possesses an appreciable tension of dissociation. The same is of course true of calcium carbonate, but this compound does not appear to be formed when only small amounts of carbon dioxide are absorbed by the calcium. If hydrogen or its compounds are present in a gas in large quantity, the spectrum-tube, after the absorption of the other gases, shows still the hydrogen lines, and refuses to become non-conducting as long as the temperature of the furnace is maintained. But if the heat is reduced, the non-conducting stage is reached at once. In one experiment 1 c.c. of hydrogen was introduced, and the heat reduced. The spectrum-tube became non-conducting in 40 seconds.

Careful experiments have shown that even after cooling an infinitesimal quantity of hydrogen remains unabsorbed. Thus if, after cooling, mercury is allowed to fill the apparatus and compress the residual gas many hundred times into a tiny spectrum-tube, a very faint hydrogen spectrum can be seen, although the spectrum-tube, even after this concentration of the gas, is still of high resistance and fluoresces brilliantly under the discharge. This residual trace will be shown to be of great value in certain experiments.

A point of very great practical importance arises out of the dissociation phenomena of calcium hydride. Different commercial specimens of electrolytic calcium exhibit differences in their behaviour which I have traced to the presence of hydride in some specimens and not in others. The presence of this hydride quite alters the characteristics of the absorption process, and although with sufficient experience it is possible to get good results in spite of the presence of hydride, this experience is apt to be dearly bought. When hydrogen is present the real absorption temperature is apt to be overstepped, for instead of a non-conducting vacuum being obtained, as it should be almost instantly with a proper specimen of metal, the dissociation tension of the hydrogen is sufficient to enable the discharge to pass. An inexperienced operator, or one accustomed only to the character of the purer metal, will, in consequence, continually increase the temperature, and the tension of the hydrogen of course increases, and may ultimately become quite measurable on a gauge. Before it is realised that the proper temperature has been far overstepped, the metal may have melted, subsequently to crack the crucible on cooling, the platinum wire may fuse or volatilise, and even the glass envelope may soften. Whereas, if instead of increasing the temperature the heat had been cut off, the non-conducting stage would have been reached in a few seconds. It was noticeable that of two specimens, one excellent and the other containing hydrogen and unsuitable, the latter was by far the more malleable and could be always detected by this test after it had accidentally got mixed with the other specimen. But this difference of properties may not have been due to the presence of the hydride. No one would use metal containing hydride wittingly, but it is well to know that by cutting off the heat, when the spectrum of the gas becomes that of hydrogen, quite satisfactory results are attainable. But the sacrifice of time and apparatus, destroyed by excessive temperature, was considerable before the differences between the specimens of metal were suspected, and the differences of behaviour understood.

Experiments were tried to see if calcium which had been strongly heated and allowed to cool in an atmosphere of helium and argon, respectively, re-evolved any trace of these gases when reheated *in vacuo*, but in each case with negative results.

V.—*Behaviour of Barium and Strontium.*

Tested under the same conditions, barium and strontium show very analogous behaviour to calcium. The specimen of barium employed had been preserved under oil, and was in the form of a granular powder. It had been prepared from the amalgam and still contained mercury. It was given a preliminary heating *in vacuo* to remove oil and some of the mercury. It commenced to absorb gases without appreciable volatilisation at a temperature notably below that required in the case of calcium. A non-conducting vacuum was usually not obtained before the metal had been allowed to cool. In the work with both barium and strontium the hydrocarbon spectrum, reminiscent of the argon gases, was very frequently observed, and was probably due to traces of the oil in which the metals had been preserved. This spectrum usually appeared when the metal was hot, and disappeared on lowering the temperature, the vacuum becoming non-conducting. Coal gas was admitted to the heated barium to a pressure of 2 to 3 mm., and was rapidly absorbed, and a non-conducting vacuum obtained without difficulty. Air introduced to about 7 mm. pressure was rapidly absorbed, except for argon, exactly as with calcium.

Barium *can* be heated to its absorbing temperature in a hard glass tube by a Bunsen burner, but the tube collapses and cracks on cooling. Under similar circumstances calcium requires a blowpipe to induce volatilisation and absorption, and the tube is completely melted and flows round the calcium in the process.

Experiments with strontium were less complete on account of the difficulty of obtaining the real metal, and on account of the small quantities that had to be used. The first sample bought as strontium proved to be potassium amalgam simply, without sufficient strontium to give a precipitate with sulphuric acid. The metal, when it was obtained, proved to be similar in properties to barium and calcium. On account of the cost only a decigramme at a time could be used, and it is very probable that its behaviour, as observed, was partly due to presence of alkali metals, oil, and mercury, and that electrolytic strontium in compact form, free from these contaminations, would exhibit a behaviour even more nearly allied to calcium. So far it has not been possible to procure this. Absorption with the sample employed seemed to start at a slightly higher temperature than with calcium, and at a high temperature some volatilisation of the metal appeared to occur. This was due probably to a trace of alkali metal. It showed to a very marked extent the phenomenon of not giving a good vacuum until it had been cooled down, and of showing hydrocarbon spectra very strongly, but this behaviour might not be shown by an oil-free specimen. It seemed hardly worth while to pursue experiments with a metal at once so costly and so impure, when a commercial process has been patented for producing the metal on a scale similar to that of calcium. But the experiments proved that, like barium and calcium, it can absorb coal gas and air, and give a non-conducting vacuum without difficulty.

VI.—*Production of High Vacua by Means of Calcium.*

From what has been said it will be seen that the apparatus described affords a ready means of obtaining a high vacuum by the use of calcium as an absorbent. Arndt, in the paper referred to, suggested its use in the production of high vacua, on account of the energetic action of the vapour on the residual air. A little consideration, however, shows that since argon is not absorbed by the reagent, air must be as rigorously as possible excluded. As is well known, the real difficulty in the production of high vacua depends not so much on the removal of all the original air, which is comparatively easily and quickly accomplished even with a pump, but on the effective removal of the gases which are condensed on the glass walls of the vessel being exhausted, and which tend to recondense in the pump when driven out of the vessel, and to introduce a kind of steady vapour pressure until they have all been removed. The value of calcium as a means of producing the highest vacua depends on its power to absorb almost instantly the gases condensed on the glass walls as soon as the latter are expelled by heating. It is, as stated, necessary to replace all the air in the apparatus before the absorption with calcium takes place, or the residual argon will prevent the vacuum obtained from being really good. The importance of this is increased by the fact that articles for exhaustion have usually to be provided with a very constricted orifice, so that they can be sealed safely after the vacuum has been obtained. As a consequence, any argon accumulating in the absorption chamber dams back the flow of absorbable gas from the vessel being exhausted, and enormously increases the time required, as the contents of the vessels have to diffuse and mix through the constricted orifice, and this process may require some minutes. Hence, in this method of high vacua production, the customary precautions must be taken against the leakage of air, if really high vacua, as distinguished from the apparently high vacua later to be considered, are desired.

If a Fleuss pump in good order is available, and new glass apparatus which has not before been exhausted is being dealt with, it suffices to continue the pumping while the apparatus in question is heated in the usual way to expel condensed gases, and so utilise the latter to replace the residual air remaining in the apparatus. Or, if a new charge of calcium, not previously heated in a vacuum, is employed, the same displacement of the air can be readily effected by the gases given out by the calcium before it attains its absorption temperature. In both cases the gases consist chiefly of carbon and hydrogen compounds and, being free from argon, serve well for the displacement of the remaining air. In other cases, or where more certainty is desirable, the complete replacement of the air may be effected by the use of a side tube containing a mixture of potassium chlorate and manganese dioxide, which evolves oxygen on warming. One or two small quantities of oxygen are admitted during the pumping, and the connection with the pump closed or sealed off before the calcium is brought into action.

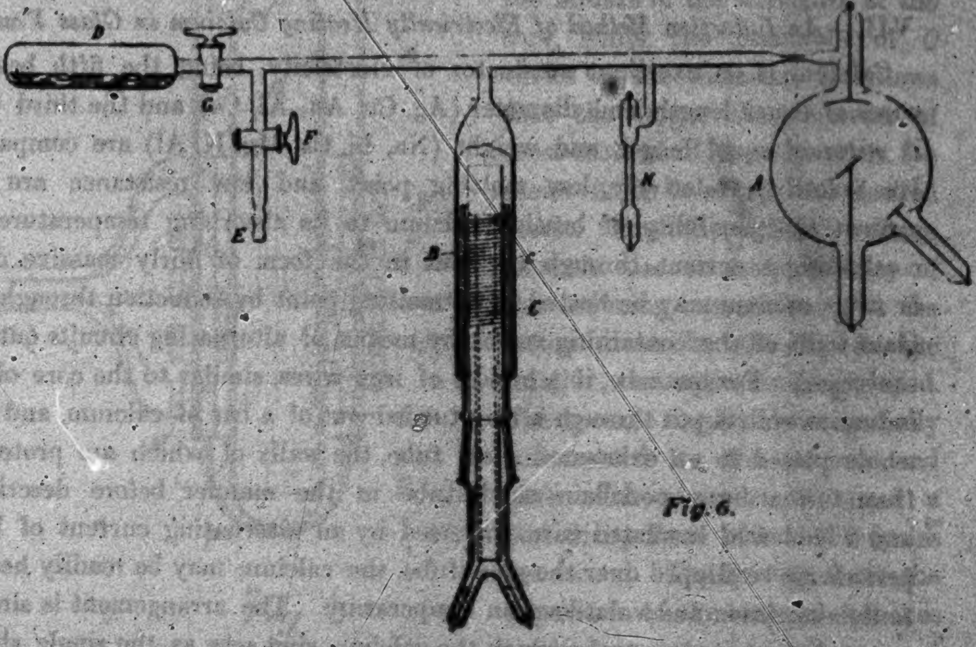

Fig. 6.

Fig. 6 shows, in diagram, an apparatus suited for the purpose of exhausting an X-ray bulb. *C* is the calcium heated by the platinum wire *c* within the glass vessel *B*. *A* is an X-ray tube, and *D* is a tube containing the oxygen mixture. The Fleuss pump is connected with *E*, and the spectrum-tube *H* is a convenience both for judging of the degree of vacuum and the character of the residual gas.

With this method, as in all methods of vacua production, the degree of rarefaction attained is the balance between the rate of absorption or removal of the gas present, and the rate of supply of fresh gas from leaks or from condensed films, or from substances such as lubricating grease or mercury which have a vapour pressure. Since the rate of absorption is extremely rapid, good results can be obtained even under poor conditions. Conditions have to be very bad indeed for any difficulty to be experienced in the production of a so-called "X-ray" or "non-conducting" vacuum. But it will be shown in the sequel that these electric discharge phenomena may be produced in vacua which could not be described as high in any other sense. With proper care the very highest vacua may be obtained by the use of calcium, as is proved by the experiment quoted in Section IV, of filling the apparatus with mercury and compressing the gaseous contents several hundred times. Personally, in crucial experiments, I should use it preferably to any other, and in the research on the positive charge carried by the α-particle* it was the final court of appeal, by which results obtained by other methods were always retried.

VII.—*An Induction Method of Electrically Heating Calcium in Glass Vessels.*

Calcium is an excellent conductor of electricity, being the fifth best if wires of equal length and diameter (Ag, Cu, Au, Al, Ca), and the third best if wires of equal length and weight (Na, Li, Ca, Mg, K, Al) are compared. Its volatility, relatively low melting point and low resistance are all against the possibility of heating calcium to its absorbing temperature by conducting a current through it. But in the form of fairly massive discs or rings calcium may be heated to its melting point by induction through the glass walls of the containing vessel by means of alternating circuits outside the vessel. For instance, if a bundle of iron wires, similar to the core of an induction coil, is put through a ring turned out of a bar of calcium, and the whole placed in an exhausted glass tube, the walls of which are protected from fusion by a porcelain shield-tube in the manner before described, and a bobbin of insulated wire traversed by an alternating current of high periodicity be slipped over the glass tube, the calcium may be readily heated to its absorption and volatilisation temperature. The arrangement is simply a step-down transformer, in which the calcium ring acts as the single short-circuited winding of the secondary, and, being of low resistance, a fraction of a volt induced in it by the magnetic flux suffices to cause the passage of a heavy current, probably of the order of a kilo-ampère, which heats it to the required high temperature. Fig. 7 shows one arrangement for this purpose.

Fig. 8 is a transverse section on the line *ww*. The iron core *M* is enclosed in a thin tube of Jena glass *P*, which is exhausted and sealed. This tube effects the double purpose of protecting the iron from excessive heat and retaining gases given off from the iron, but can be dispensed with. *C* is the calcium ring, *K* is the porcelain shield-tube, *B* is the outer glass containing tube, *N* is the external circuit through which the inducing current is passed. As the heat given out from the calcium is considerable and apt to injure insulating material, it is convenient to employ, instead of a bobbin of insulated wire of many turns, a few turns of stout, bare, copper bar or tube, and to obtain the inducing current from the secondary of a step-down transformer not shown in the drawing. Since the magnetic flux, and therefore the inducing voltage in *C*, varies as the square of the diameter of the core, while the resistance of *C* varies as the diameter, it follows that the larger the diameter of cross-section of the apparatus the easier it is to obtain the desired result. But the induced voltage depends also on the periodicity of the inducing current, so that the latter must be the higher the smaller the apparatus employed. The dynamo employed was specially constructed for the purpose and gave with variation of speed a periodicity from 200 to 400 cycles per second. The drawing shows the apparatus to the scale of 6 inches to the foot.

---

* 'Nature,' August 2, 1906, p. 316.

Fig. 7.

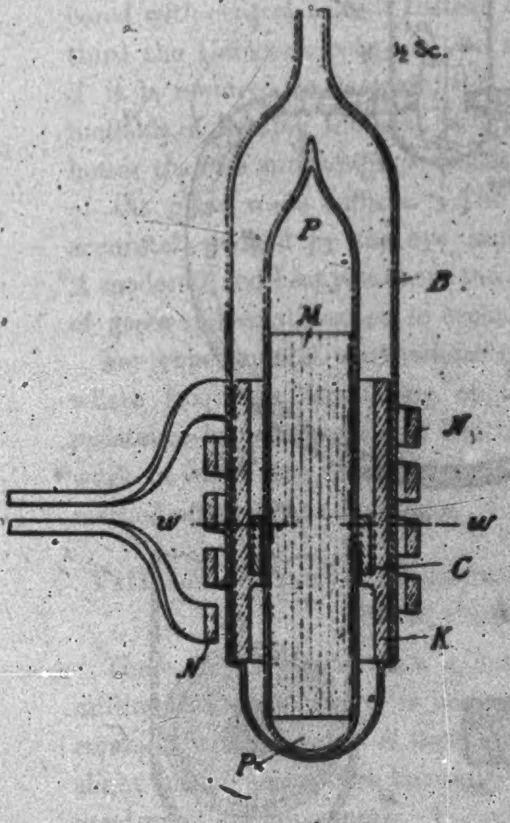

Fig. 8.

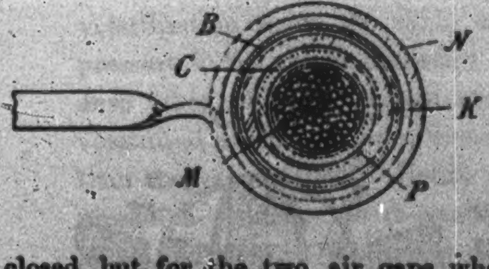

Another form of apparatus is shown in fig. 9, to the scale of 3 inches to the foot. It differs from the last mainly in that the magnetic circuit, composed of the iron strips or wires *M*, *M* *M* *M*, is closed but for the two air gaps where the glass walls of the containing vessel penetrate it. The use of the step-down transformer is unnecessary, because the inducing bobbins, represented diagrammatically by the circuit *N N N N*, are far enough removed from the source of heat not to be damaged

The part within the glass containing vessel is shown to twice the scale (6 inches to the foot) in fig. 10. Fig. 11 is a section of the same. Figs. 12 and 13 are transverse sections in vertical and horizontal planes respectively. *C* is a disc of calcium bored with a central hole, through which passes the bundle of iron wires *M M*. P_2 P_1 are two porcelain crucible lids bored with central holes. Instead of the disc of calcium shown, a disc one-third the thickness between two similar discs of copper may be employed if it is required to increase the conductivity. Since in these induction methods of heating the heat is developed in the reagent itself, the latter is hotter than its surroundings, which is a great advantage, as far less screening of the glass walls suffices. The temperature of the metal can be very accurately judged by the eye, and must be kept below the melting point. A moderate red-heat just above the cherry-red stage is necessary for absorption of gases and volatilisation to occur.

For experimental work where cost is not the primary consideration, and where frequent dismantling of the apparatus is rendered necessary, the resistance-furnace method of heating is to be preferred. But for prolonged work in which the object is simply to obtain a high vacuum, the induction method offers great advantages.

VIII.—*Some Practical Considerations in the Use of Calcium as an Absorbent for the Production of High Vacua.*

There is no doubt that a low initial pressure, not exceeding a few millimetres of mercury, is as essential a condition in causing calcium to combine with gases as a high temperature. As Arndt showed, there is a slight initial absorption below the volatilisation temperature, and this is of great practical importance. For rapid and continuous absorption volatilisation is essential. But in a case where the initial pressure is above that at which volatilisation occurs the slight initial action is often sufficient to lower the pressure to the extent necessary for the formation of vapour. When this has once taken place subsequent absorption is much facilitated, for the film of volatilised metal continues, even in the cold, to absorb, although more slowly than the vapour itself. Hence once volatilisation has taken place there is present a tendency to re-establish the condition for further vaporisation. When, however, a mixture with an unabsorbable constituent, for example, air, is being absorbed, the accumulation of this constituent hinders the volatilisation and further absorption by the calcium. Another factor operating in the same direction is the increased loss of heat by convection currents in the presence of a gas, tending to lower the temperature of the reagent and furnace, and to lower the resistance of the latter. In the usual case, where this resistance is small compared to the external resistance in the circuit, the fraction of the electrical energy dissipated within the furnace is also lowered, and so the temperature falls from a double cause. If water vapour is present the action becomes extremely marked on account of the great conductivity of this vapour to heat. The current necessary to raise the temperature in this case may be so great that, unless promptly reduced when absorption commences, the heating circuit is apt to be destroyed.

Under proper conditions of working the calcium should never be melted, although it may be volatilised completely and redeposited on the cooler part of the tube as a compact tube or ring difficult to remove by mechanical means. Used porcelain tubes should never be exposed to the air or treated with water or dilute acids, as they readily crack under this treatment. Immersion in concentrated hydrochloric acid usually serves to dissolve the volatilised metal without cracking the tube, but with the liberation of the spontaneously inflammable silicon hydride. If the calcium is melted in the tube the latter usually cracks on cooling, so that for many reasons suitable iron tubes would be better than porcelain. The narrow margin of temperature, 70° C. according to Arndt, between the volatilisation and melting point need, however, never be exceeded when experience has been gained and suitable metal is employed. The presence of hydride in the metal acts so prejudicially largely because the dissociation tension of hydrogen lessens the volatilisation and reduces still further this narrow margin, so that the melting point is the more likely to be overstepped. These conclusions as to the conditions under which calcium should be employed as an absorbent have been arrived at after over a year's continuous use of the method.

The following experiment on the effect of vapour of grease and of a very constricted orifice between the vessel being exhausted and the absorption chamber is instructive. An X-ray bulb was connected to the calcium absorption apparatus provided with a ground-joint. The latter was lubricated by the well-known mixture of rubber, paraffin-wax and vaseline, employed by Sir W. Ramsay. A spectrum-tube was provided and the apparatus exhausted by the Fleuss pump, and the connection with the latter sealed off. The calcium was brought into action and a vacuum corresponding to an alternative spark-gap of 15 cm. obtained in the X-ray tube. It was then left over night in connection with the furnace, so that the vapour from the grease of the ground-joint could exert its full effect. In the morning the vacuum was so low that there was no trace of green fluorescence in the tube. The calcium was heated and allowed to cool. In 40 minutes the 15-cm. alternative spark-gap was again attained.

Then, hour by hour, the vacuum slowly deteriorated till the alternative spark-gap was *nil* and the green fluorescence disappeared. This process of heating the calcium and leaving till the vacuum went right down was repeated day by day for a week. It was noticed that it always took 40 minutes after heating the calcium before the 15-cm. spark-gap was regained, and this period represented, as numerous experiments with the same tube show, the time taken by the gases to flow out of the X-ray bulb through the constricted orifice when a practically perfect vacuum existed on the other side. It happened that the constriction was unusually and unnecessarily narrow, such as an amateur not realising the importance of it would make, but the necessity of this constriction, where the tube is ultimately to be sealed off, imposes a natural limit on the time taken for the exhaustion, however rapid a method of absorption is employed. In this experiment the spectrum in the Plücker tube, when the vacuum was low, was due to hydrocarbons, and nitrogen was never seen. That there was no appreciable leak of air was also shown by the fact that even at the end of a week no lines of argon could be seen. This shows that the deterioration of the vacuum was simply due to vapour being slowly given off from the grease used for lubrication. A properly constructed ground-joint is wonderfully air-tight. I may mention that in 1904 I constructed one of Strutt's so-called radium clocks with a ground-joint similar to those employed in the furnaces. The period of the clock is the same now as when constructed, and it has worked continuously without re-exhaustion, proving conclusively that no trace of air has leaked through the ground-joint. Hence, in the calcium method, where the vapours of lubricants are absorbed with rapidity, as many taps, ground-joints and similar conveniences as desired may be employed without harm, provided they are well lubricated and never get heated, and that the apparatus being exhausted is sealed off as soon as the high vacuum is attained.

IX.—*Quantity of Argon Detectable by the Spectroscope.*

If air is admitted to heated calcium the oxygen and nitrogen are absorbed almost instantly, and the argon and its companions in the atmosphere remain behind in a state of great purity and freedom from ordinary polyatomic gases. In the apparatus used an arrangement of two taps for admitting known small quantities of gas was joined to the apparatus for the absorption of gases by calcium. The space between the taps was 0·13 c.c. and the total volume of the apparatus was 123 c.c. The partial pressure of argon is 0·0094 of the atmospheric, or 7·1 mm. Each quantity or "dose" therefore of 0·13 c.c. of air admitted to the apparatus corresponds to a pressure of argon of 0·0075 mm. of mercury. The vacuum-tube employed was an ordinary Plücker tube, with aluminium electrodes, of about 4·5 c.c. capacity. It was found that no trace of the argon spectrum could be seen in the tube, and no discharge would pass through until three doses of air had been admitted and absorbed. At this stage the group of greens and the orange line in the spectrum were faintly visible. With four doses the red lines were visible momentarily as the nitrogen spectrum faded, and with five doses these became permanent. After 10 doses (1·3 c.c.) of air had been introduced, the whole argon spectrum was brilliant; 4·5 c.c. were so added in small quantities and then 3 c.c. at once. In one minute the nitrogen spectrum began to clear and 1·5 minutes the argon reds were visible. In two minutes nitrogen had disappeared, and in under three minutes only argon and hydrogen were visible. The hydrogen disappeared when the heat of the furnace was reduced and the tube, giving a perfect argon spectrum, was sealed off as a memento of the experiment.

In another experiment the volume of the apparatus was 100 c.c., and 12 c.c. of air were admitted in one quantity after the calcium had been heated *in vacuo* to the absorbing temperature. This was absorbed without difficulty. The residual argon must have exerted about 1 mm. pressure. Yet the spectrum-tube showed brilliant green fluorescence. A tap was opened and the argon allowed to flow into a similar volume of 100 c.c. which had previously been perfectly exhausted. The pressure was thus reduced to about 0·5 mm., and at this stage the spectrum-tube had a resistance equivalent to an alternative spark-gap of 5 mm.

It follows from these experiments that below a pressure of 1/50 of a millimetre no discharge can be sent through a tube containing argon. At this pressure the greens and orange become faintly visible, and at 1/25 of a millimetre the reds appear. At 0·5 mm. the resistance of the tube is still so high that the discharge prefers to jump an air-gap 5 mm. long, while at a pressure of 1 mm. the tube is brightly fluorescent.

It was found that the substitution for the ordinary vacuum-tube of one of minimal volume with platinum electrodes did not much affect the pressure of gas at which the spectrum became visible. With a tube of 0·3 c.c. volume, which is as small as it is convenient to employ, a quantity of argon less than 1/100 of a cubic millimetre, measured at normal temperature and pressure, could not be detected by the spectroscope. This applies to the pure gas in the absence of almost every trace of the relatively far more conducting polyatomic gases. As in the case of helium, to be considered, smaller quantities of argon could be detected in presence of hydrogen or other polyatomic gas.

X.—*Misapprehensions Regarding High Vacua.*

The foregoing experiments with argon, and others of a similar character with other monatomic gases, serve to show that the characteristics of the electric discharge may prove a very faulty guide to the degree of a vacuum. The terms "X-ray vacuum," "fluorescent vacuum," etc., afford, apart from the knowledge of the character of the residual gas, no indication at all of the actual pressure. For if it happens that the residual gas is a pure monatomic gas, the fluorescent stage and even the non-conducting stage are reached at pressures within the range of the mercury barometer. These considerations serve to connect numerous isolated facts familiar to those who have worked with high vacua. Thus it is well known that to pump out a spectrum-tube with a mercury pump takes far less time if the gas pumped out is argon or helium than if air or hydrogen has been present.

[*Added.*—It is also well known that in vacuum-tubes filled with inert gases great heating of the electrodes occurs, even when these are made of aluminium, accompanied with the rapid disintegration of the electrode and the volatilisation of the aluminium. At the same time a rapid exhaustion of the supply of gas apparently takes place, the vacuum appears to rise, the tube rapidly becomes fluorescent with use, and the resistance increases to the non-conducting point at which no discharge can be passed through the tube. In the past this has been attributed to the absorption of the gas by the electrodes and the walls on which the volatilised aluminium is deposited. The advantages of aluminium over other metals, such as platinum, have been ascribed to a more rapid absorption in the case of the heavier metals.[†] Attempts to recover the gas supposed to be absorbed, by heating the apparatus, solution of the metal electrodes, etc., have not been successful, as only a trace of the gas is recovered in this way.

The true explanation of the phenomenon is quite different, and follows simply from the experiments given in section IX for argon, and similar ones in sections XI and XII for helium. The inert gases are not absorbed, but remain in undiminished quantity in the gaseous state in the tube, but the traces of ordinary chemically active gases always present, initially or introduced from the electrodes during the discharge, are absorbed, and the tube becomes in consequence non-conducting. The experiments of Skinner have an important bearing on this question, and in his most recent paper[‡] he summarises his conclusions. When a current is passed through a vacuum-tube, entirely independently of the nature or amount of gas filling the tube, hydrogen is evolved from the cathode and absorbed by the anode at a rate initially equal to that required by Faraday's law. Aluminium and magnesium cathodes give out hydrogen much more freely than the denser

---

[†] Compare Travers, 'Study of Gases,' p. 299.

[‡] 'Phil. Mag.,' November, 1906, p. 481.

metals, but the rate of *evolution* from the cathode rapidly falls off as the supply of gas in the surface layers of the metal is exhausted. If the tube is allowed a rest the initial rate is recovered. When a continuous discharge is passed through any tube, therefore, the vacuum improves, for the rate of absorption by the anode gains on the rate of evolution from the cathode, and this should suffice to explain the well-known improvement with use in the vacuum of an X-ray tube. According to Skinner, helium and argon are *not* absorbed by the electrodes, hence the rapid exhaustion or "running out" of the tube and the advantages of the aluminium electrode are to be explained only in the manner indicated. It is intended to try, by passing a unidirectional current through a tube filled with inert gas, to what gas pressure the non-conducting stage can be pushed. It is not a little remarkable from the theoretical point of view that helium, which conducts so much more readily than any other gas under usual conditions at high pressure, should exhibit the peculiar behaviour it does at low pressure in a state of purity.

Frequently in the work on the production of helium from radium, in conjunction with Sir William Ramsay, it was noticed when "running" a spectrum-tube to absorb nitrogen and reveal helium, if present, that, although a severe and prolonged running might be necessary to absorb the nitrogen, it always "ran out" first, and helium, however minute in quantity, showed itself, if present, as the nitrogen spectrum faded. When, however, the nitrogen spectrum had completely faded, which it did usually with great rapidity once it commenced to weaken visibly, the helium "ran out" almost instantly, if only in minute quantity, and the tube refused to conduct the discharge. This sharp preferential absorption, as it seemed, of the nitrogen first by the electrodes, so that, even after a quarter of an hour's hard running, the helium would survive, instantly to disappear as soon as the nitrogen faded, always seemed to me almost providential, until, recently, the true explanation became obvious.]

The explanation is also to hand why the presence of mercury vapour affects the action of the mercury pump so little. The vapour pressure of mercury at room temperature is between 1/500 and 1/1000 of a millimetre. In the case of hydrogen or carbon dioxide it is probable that this pressure would be sufficient to conduct the discharge and prevent the vacuum appearing very high to the electrical test. That "high vacua" can be obtained at all by the mercury pump is probably due to the fact that mercury vapour is monatomic.

Similar considerations apply to the vacua so readily and simply obtained by the use of charcoal cooled in liquid air according to the method now largely used in scientific investigation and first employed by Sir James Dewar.[*] It

---

[*] 'Roy. Soc. Proc.' A, 1904, vol. 74, pp. 122—131.

happens here also, as in the case of the calcium method, that the unabsorbed gases are monatomic. At liquid air temperature the helium and neon in the air remain very largely unabsorbed by charcoal. Sir W. Ramsay* has determined in this way the proportion of these gases in the atmosphere and found 17 parts per million of the two gases together. An earlier determination made by Dewar,† without the use of charcoal, was identical with this. The figures obtained by Ramsay, however, are for the total gases left uncondensed by charcoal at liquid air temperature, and have a direct bearing on the present question. Now, as Lord Blythswood and Allen‡ have shown, there is no difficulty in exhausting an X-ray bulb by the use of cooled charcoal from atmospheric pressure to the point at which it is difficult to force a discharge through the bulb. Yet the pressure of the helium and neon in the bulb must be 17 millionths of the initial pressure or about 1/75 of a millimetre. This result, although appearing strange by itself, is consistent with the experiment on the pressure of argon necessary to allow the discharge to pass. When any method of measuring the amount of gas remaining in the exhausted space other than the electrical is employed, the deficiencies of the non-conducting vacuum produced by cooled charcoal, when the vessel was originally filled with air at atmospheric pressure, become at once apparent. If, for example, the degree of vacuum obtained is measured by the rate of evaporation of liquid air in a Dewar flask, then the presence of these residual monatomic gases becomes all important. Experiments of a quantitative character on this subject are being made by Mr. Berry§ in this laboratory.

[*Added.*—Lord Blythswood and H. S. Allen‖ after showing, in the first part of their paper, that an X-ray bulb could be exhausted by cooled charcoal from atmospheric pressure in one hour to "a vacuum so good that the tube had to be heated in order to allow the discharge to pass through it," describe in the second part experiments in which the final pressures realised were measured by means of a McLeod gauge. When the apparatus was exhausted by a Fleuss pump initially to 40 mm., the final pressure attained was 0·0008 mm., whereas, starting from a pressure nearly atmospheric, the final pressure attained was ten times as great. They point out the importance of the preliminary exhaustion when an extremely high vacuum is required, owing to the presence of the less easily condensible gases, hydrogen, helium, and neon, in the air, but do not refer to the apparent inconsistency between the results with the McLeod gauge and their earlier ones with the electric discharge test.

§ See addendum to this paper.

‖ *Loc. cit.*

I was present at the meeting of the Philosophical Society of Glasgow (March 22, 1906), when Mr. Allen showed experimentally the exhaustion of an X-ray bulb from atmospheric pressure by cooled charcoal, and I was much impressed at the time with the apparent inconsistency between this result and the recent measurements of Sir W. Ramsay already cited.

The allusions in this section to the results of use of the charcoal method have reference solely to the phenomenon of the bad conducting quality of the residual inert gases that remain when air is absorbed from atmospheric pressure by use of charcoal or other methods. The question of the degree of vacuum produced under proper conditions for obtaining the best results is, of course, entirely different. Although the test of non-conductance, which has, so far, been relied upon too implicitly for gauging the goodness of the vacuum,* is useless, and may be actively misleading in the case of vacua obtained by the use of cooled charcoal without preliminary exhaustion by a pump, there is no doubt at all that, with suitable procedure, this method can give a very high degree of exhaustion.†]

XI.—*Quantity of Pure Helium Detectable by the Spectroscope.*

Mixtures of known composition were made of helium and oxygen, and known quantities introduced into the calcium absorbing apparatus of known volume. The pressure of the residual helium could thus be calculated. In one case 0·13 c.c. of helium was made up to 104 c.c. with oxygen, so that the mixture contained 1/8 per cent. of helium. Successive quantities, each of 0·13 c.c., were introduced into the apparatus, the volume of which was 89 c.c., including an ordinary Plücker tube of volume 4·5 c.c. The following observations are extracted from the note-book. The "quantities" referred to are each 0·13 c.c. of the mixture, and the test of non-conductance was an alternative spark-gap of 2·5 cm. in air.

1st quantity.—Glimpse of D_3 for a fraction of a second as the oxygen spectrum suddenly cleared and tube became non-conducting.

2nd quantity.—D_3 clear while the tube conducted, which was but momentarily.

3rd quantity.—D_3 very pure and distinct, but tube became non-conducting.

5th quantity.—D_3 at first brighter than the mercury yellows.

6th quantity.—D_3 the brightest line at first except for the oxygen orange-red line.

---

* Compare also G. Claude and René J. Lévy, 'Comptes Rendus,' 1906, vol. 142, p. 876.

† *Cf.* the experiments described by Mr. Berry in the addendum to this paper.

7th quantity.—Just before the non-conducting point the general spectrum was plainly recognisable as helium.

8th quantity.—The brighter helium red (6677) visible.

9th quantity.—The two blues and violet seen.

10th quantity.—First glimpse of the peacock-green line (5016).

Tube took four minutes before it became non-conducting.

11th quantity.—Eight minutes before non-conductance.

13th quantity.—The helium spectrum was now quite good while it lasted, but the tube became non-conducting in three minutes.

The experiment was continued without much alteration up to the point at which 35 quantities had been added. The helium spectrum was plain, and indeed brilliant, so long as the tube conducted, but always a point was reached at which the discharge refused to pass. Diffusion was hastened by alternately heating and cooling the furnace. At the 35th quantity the tube conducted one way of the commutator and not the other, and this was taken as the limiting value. Later in the day and next morning the tube showed the same result. The discharge just passed, but the spectrum was feeble. The line D_3 was clear and the peacock-green exceedingly faint. These were the only helium lines visible.

The pressure of helium corresponding to each dose is 0·0014 mm. and to 35 doses 0·049 mm. It is thus clear that pure helium at a pressure of less than 1/20 mm. is non-conducting to the discharge, while far less than this can be detected in presence of other gases. Like mercury vapour and krypton, a very small trace is visible in the spectrum of another gas. In the above experiments the D_3 line was visible plainly when only a single dose was added, so that to get the minimum quantity detectable a fresh series of experiments with more dilute mixtures was necessary.

XII.—*Most Favourable Conditions for the Detection of Infinitesimal Quantities of Helium.*

Collie* states that in presence of large quantities of mercury vapour the blue helium line, 4922, is the most delicate test for helium, and can easily be seen when none of the other helium lines are visible. It is likely, however, that the author mistook for helium a line in the spectrum of mercury which has the wave-length 4916·4 (Stark) and which is prominent in the mercury vapour-lamp spectrum. It is not often seen in the Plücker tube, except when the latter is warm and liquid mercury is present, so that the vapour pressure of the mercury is considerable. Collie has suggested for the calibration of spectroscopes a tube containing liquid mercury, helium and hydrogen, as the spectrum consists of a large number of standard lines fairly equally distributed throughout the length of the spectrum. In such a tube I kept the blue line in question under close observation in a good spectroscope. With a feeble discharge, the tube cold and the mercury spectrum faint, this line was single and due to helium only. As the strength of the discharge was increased, and the tube warmed, the mercury spectrum intensified, and a second line became visible on the more refrangible side of the helium line and distant from it roughly about as far as D_3 is distant from D_2. On still further increasing the strength of discharge the helium line disappeared entirely, and the line was again single and due to mercury only. On diminishing the discharge and allowing the mercury vapour to recondense, the less refrangible line reappeared and grew in strength as the other faded, and finally alone remained visible. Thus, it is clear that so far from enhancing the strength of the helium line, 4922, the presence of mercury serves to mask it completely even in presence of considerable quantities of helium. This line, 4916, is seen equally well in a tube containing mercury in which no helium has been introduced. Under no conditions tried has the line 4922 been seen when D_3 was invisible. The latter is by far the most delicate test for the presence of helium, and becomes visible with a quantity many times less than suffices to develop any other line in the spectrum.

---

* 'Roy. Soc. Proc.,' 1901, vol. 71, p. 25.

Some experiments with various kinds and sizes of spectrum-tube, some with aluminium and others with platinum electrodes, showed that with minimal quantities of helium at similar *pressure* it is slightly easier to detect the D_3 line in the ordinary Plücker tube of volume 4·5 c.c. than in a tube of minimum volume. But the difference is not great, and is mainly due to the sodium lines from the glass being more prominent in a tiny tube masking the D_3 line. Certainly, when the object is to detect the smallest possible *quantity* of helium, the tube should be of as small volume as possible. A series of experiments was tried in which quantities of helium, far smaller than those necessary to allow the discharge to pass when in the pure state, were examined in presence of hydrogen and oxygen. A mixture containing 0·015 per cent. of helium with oxygen was prepared by the principle of successive dilutions. Known quantities were introduced into the calcium absorption apparatus of known volume. After the oxygen had been completely absorbed, connection between the spectrum-tube and the absorption chamber was closed, and traces of oxygen and hydrogen introduced into the gas in the spectrum-tube. This was accomplished by heating a trace of solid potash, previously fused and freed from water, *in vacuo*, or by momentarily raising to redness a spiral of platinum wire by means of a current. It does not appear to make much difference which gas is added to conduct the discharge. After the first momentary heating platinum gives oxygen free from hydrogen. The potash gives hydrogen, doubtless as water vapour. The function of this gas is merely to cause the discharge to pass. Once established, a large part, perhaps the larger part, of the current is carried by the helium, the spectrum of which, under these conditions, appears with extraordinarily minute quantities.

With an ordinary Plücker tube and an apparatus of volume 111 c.c. after three doses, each of 0·13 c.c. of the 0·015-per-cent. mixture, D_3 was but momentarily visible, and could not be again brought out by introducing oxygen or hydrogen. With four doses D_3 was faint but clear and permanent, and this may be taken as the extreme limit of visibility. The partial pressure, due to the helium at this stage, is only 1/100 of that necessary to conduct the discharge when pure, being 0·0005 mm. as compared with 0·05 mm. for the case of the pure gas discussed in the last section.*

If a vacuum-tube of 0·3 c.c. volume is used, it follows that a quantity of helium, 1/4000000 part of a cubic centimetre, measured at normal temperature and pressure, would be within the range of detection by the spectroscope. For safety a margin of twice this quantity should be allowed, or 1/2000 of a cubic millimetre. This quantity weighs 10^{-10} gramme, and contains about 2×10^{13} atoms. The delicacy of the test may be indicated by the following consideration. It can be calculated on the assumption that the α-particle is an atom of helium, that a kilogramme of uranium nitrate would generate 1 c.c. of helium in a period of about 5000 years. The amount of helium produced in a single day should be within the range of spectroscopic detection. Researches on the production of helium from uranium and thorium have been in progress for some time, and it is hoped, now that the ground is cleared, that the matter will soon be put to a definite quantitative test.

In the above experiments the actual quantity of helium used was, of course, many times the amount finally examined in the spectrum-tube. It is easy, however, to fill the absorption chamber after cooling completely with mercury, and to compress the gas into the spectrum-tube. In this operation the minute quantity of hydrogen left unabsorbed by the calcium is, after the compression, just of the right amount to conduct the discharge and to reveal any trace of helium without any additional arrangement.

---

* [The point was raised in the discussion of the paper, how far it had been actually proved that the inert gases were not absorbed, at least in part, by the walls and electrodes. The last experiment answers this question, for in a tube containing only one-hundredth of the quantity of helium necessary to conduct the discharge in the pure state, the helium spectrum may be brought out afresh by introducing a minute quantity of hydrogen or oxygen, which would not have been the case if the helium had been absorbed when the tube became non-conducting.]

As an example of an actual experiment, one may be taken from the note-book from an examination of the gases present in native platinum. On the view that the scarcity of an element, after prolonged and extensive search for it, justifies the suspicion that it may be a member of a disintegration series, it was thought possible that evidence of such disintegration might appear in the presence of rare gases in platinum, as is the case with the radio-active minerals. Messrs. Johnson and Matthey very kindly lent me as much native platinum as required, and I desire to acknowledge my indebtedness to them for their kindness.

In one experiment a quantity of about 300 grammes was heated in a porcelain tube in an electric oven to 1200° C., and the gases passed into a calcium absorption chamber of the usual kind provided with a tiny spectrum-tube at the upper end. A trace of carbon dioxide, from the walls probably, first came off. Then nitrogen appeared, and, as the temperature approached 800° C., carbon dioxide in quantity. On closing the connection with the platinum and absorbing the gas with calcium, the spectrum-tube became quite non-conducting. These operations were repeated, the gas evolved being admitted and absorbed in stages. When the electric oven had reached a temperature of 1000° C., a momentary glimpse of the D_3 line was seen. At 1100° C. the peacock-green line was picked up, and the more prominent of the two reds seen extremely faintly. On forcing the discharge the argon greens could be faintly made out in a Ramsay pocket spectroscope. When the oven reached 1200° C., a large quantity of carbon dioxide had accumulated. This was admitted to the absorption chamber, and the connection sealed and the heating of the platinum stopped. On cooling the calcium after absorbing the gases, the spectrum-tube was on the verge of non-conductance, but extremely faint helium could be detected. Mercury was admitted and the contents compressed completely into the tiny spectrum-tube. The helium spectrum was now reasonably bright, all the lines being visible, together with the hydrogen red and the mercury lines. With the pocket spectroscope argon could just be detected. It was estimated from the appearance of the discharge at various stages of the compression that about 1/5 of a cubic millimetre of helium was present, a quantity 400 times as much as could have been detected, yet only representing 1/15000000 per cent. by weight of the platinum. The experiment lasted but two hours, and is given merely as an example of the ease with which an infinitesimal quantity of helium may be separated from large amounts of other gases by means of calcium, and its quantity estimated with fair probability. No weight is to be put on the result as indicating the origin of the helium. As a matter of fact, the native platinum was quite distinctly though feebly radio-active, 300 grammes of it in an electroscope producing an effect equivalent to 0·07 milligramme of uranium oxide. Clevite usually contains about 2 c.c. of helium per gramme, and is usually of about the same activity as uranium oxide. The platinum contained about 3,000,000 times less helium, and was about 4,000,000 times less radio-active than clevite, so that there is no reason to go further to explain the source of the helium than to suppose that a trace of some radio-element is present in native platinum.

Appendix.—*Results of Gauging High Vacua by the Evaporation Test.*

By Arthur John Berry.

In this note the results of some experiments, on the rate of evaporation of liquid air contained in a Dewar vessel exhausted in different ways, are described with the view to showing that this test may be used as a means of gauging the degree of vacuum produced by different processes. Owing to various causes the research has not been carried as far as it was intended, but one set of measurements, complete in themselves, have been obtained, which bear out in a clear manner one of the points discussed by Mr. Soddy in the paper preceding. Starting with a vessel filled with air at atmospheric pressure, there is no difficulty, by using the method of Sir James Dewar to produce a vacuum therein, in obtaining a vacuum apparently perfect, so far as the electric discharge test can indicate, provided that a sufficiency of charcoal is employed. It was of interest to compare the rate of evaporation of liquid air in a Dewar vessel exhausted in this manner with the rate in the same vessel exhausted also by Dewar's method, but in which the air had been first removed by an auxiliary pump. Although the electrical test reveals no difference in the degree of vacuum obtained in the two methods, it is to be expected that the thermal test will show a far higher vacuum by the second method than by the first, owing to the residuum of non-conducting inert gases left by the first method.* This expectation has been fully borne out by the experiments.

The vessel employed was of about 1 litre capacity, globular in form, and silvered on the two inner walls. During the exhaustions it was placed in an inverted position in an air oven, and the temperature maintained at

---

* Compare Lord Blythswood and H. S. Allen, 'Phil. Mag.,' October, 1905, p. 497.

350° C. A vacuum-tube served to indicate the progress of the exhaustion. At the completion of each exhaustion it was filled with liquid air, and kept in an ice chest to keep the external temperature constant. The vessel was weighed at regular intervals to determine the rate of evaporation of the air. Three different methods of exhaustion, designated throughout I, II, III, were employed.

I. In the first the exhaustion was performed by the mercury-pump. A Töpler pump of ordinary pattern, worked by hand, was used, and pumping was continued from four to five hours while the vessel was heated in the air oven. The pump had a capacity of about 450 c.c., and was provided with a phosphorus pentoxide tube and tap. The results of two similar experiments agreed well among themselves, and in the table the second of the two, which was slightly the better, is alone included.

II. In the second method the apparatus was exhausted from atmospheric pressure by cooled charcoal. As in the experiments of Lord Blythswood and H. S. Allen,* two separate charcoal bulbs were employed, the one with 97 grammes and the other with 70 grammes of charcoal freshly prepared from cocoanut shells. The first bulb alone reduced the pressure from atmospheric to the fluorescent stage in 30 minutes, and was then cut out and the second bulb brought into action. The absorption was continued one and a-half hours further, and the vessel sealed off. No discharge could be sent through the vacuum-tube at this stage.

III. The same vessel was exhausted by a duplex Fleuss pump of large size, mechanically driven, and during the action of the pump the charcoal was well heated. In this way carbon dioxide is expelled from the charcoal, and the last traces of air are swept out. It was found in a separate experiment that little or no difference was produced in the result by the displacement of the last of the air by oxygen during pumping. In this method only one charcoal bulb was used, which was connected direct by a glass tube without taps to the vessel being exhausted. The connection with the pump was sealed after the removal of the air was judged complete, and the absorption by charcoal continued for two and a-half hours.

The following table shows the results of the three methods. Weighings were taken at intervals of either 6 or 12 hours. The first column shows the time in hours from the first weighing, and the total weight of liquid air initially present in the three experiments is indicated in the first line. The succeeding lines indicate the amount that has evaporated in the 6- or 12-hour interval from the previous weighing:—

---

* *Loc. cit.*

Hours.	I.*	II.	III.
0	972 grammes	954 grammes	979 grammes
12	2 × 54·5	2 × 63	2 × 40·5
18	54	62·[illegible]	40
24	54	60	39
36	2 × 54·5	2 × 60	2 × 39
42	54	59	39
48	55	58	37
60	2 × 56	2 × 57·5	2 × 37
66	56	57	37
72	57	56	37
84	2 × 58·5	2 × 56	2 × 37
90	58	55	38
96	59 (78 remaining)	56 (18 remaining)	36
108	—	—	2 × 37
114	—	—	38
120	—	—	36
132	—	—	2 × 36
138	—	—	36
144	—	—	37 (78 remaining)

It will be seen at a glance that whereas the vacuum resulting in the second method, by cooled charcoal, but starting from atmospheric pressure, is inferior to that produced by a simple mercury pump, that obtained in the third method, by charcoal after removal of the air, is by far the best of the three. After six days 78 grammes of liquid air out of the original kilogramme remain in the vessel.

In conclusion, I desire to take this opportunity of expressing my indebtedness to Mr. Soddy, at whose suggestion the research was undertaken, for placing the apparatus required at my disposal and for many valuable suggestions.

---

* The slight increase in the rate of evaporation during this experiment is due to a shortage in the supply of ice in the ice-chest. In the other two experiments the chest was kept well filled.

Wehnelt Cathode in High Vacuum.

A remark to the article of Fred. Soddy[1])

By J. E. Lilienfeld. 193

The observation that forms the basis of the above treatise is that with the decrease of the gas pressure from a definite limit the voltage which is necessary to start a discharge between a Wehnelt cathode and any anode markedly increases. This signifies according to the author (Soddy) that in this region of pressure "the Wehnelt cathode loses its activity."

Now I have shown in two publications [2]) one of which antedates by one year the above named article, that with the gas discharge in high vacuum obtained with special care a series of important phenomena appear. Already in the first of the above mentioned publications (pages 634-635) I have described as the outstanding characteristic the rise of the potential drop in the positive column with decreasing pressure in the range of pressure mentioned. I showed therein that this fact is diametrically opposite to that observed with otherwise customary vacua. This condition was found to be entirely independent of the nature of the electrodes (which "in a part of the investigation were large aluminum electrodes, page 631") and indicated that "it is not exclusively the electrons emitted from the oxide cathode which, as was often assumed, determined the discharge in high vacua, but that the discharge depends essentially on a second factor. I pointed out more specifically in my second paper this view, that in consequence of the absence of the last traces of gas the number (volume density) of the negative electrons supplying the current becomes great in comparison with the number of gas molecules per unit volume, so that therefore the tendency exists for the formation of the greatest possible negative space charge" - which opposes the current transport by the negative electrons.

The higher the vacuum, the greater the current density3), the more prominent this new kind of discharge becomes - while the energy consumed in the Wehnelt cathode itself for the production of the discharge with constant current density does not markedly increase. In this sense I believe that the view does not apply that "in high vacuum the Wehnelt cathode loses its activity." On the contrary, concerning the phenomenon in question, we have to do with an important factor which is very general with discharges in extreme vacua.

FRICTION IN GASES AT LOW PRESSURES.

BY J. L. HOGG.

Presented by John Trowbridge June 29, 1909; received June 29, 1909.

UNDER the title "Friction and Force due to Transpiration as dependent on Pressure in Gases," there was published[1] some time ago an account of some experiments made to determine the relation between the friction of a gas and the pressure in it, and also the relation between the force exerted by a lamp on a mica vane, blackened on the face which is turned towards the lamp, and the mean pressure in the gas in which the vane is placed. The three-fold purpose of the investigation was pointed out there, viz.:

First, to investigate the relation between friction and pressure where the pressures were so small that "slip" is appreciable; second, to determine the relation of transpiration force in the special form of apparatus described there;[2] and, third, to make use, if possible, of these two relations to test the validity of the McLeod gauge measurements of pressure, and, if these measurements should prove unreliable, to make use of one of the relations named above to measure gas pressure.

There has been much delay in carrying out the investigation with the apparatus improved in the manner indicated in the closing paragraphs of that paper, but now some results have been obtained in so far as the friction problem is concerned.

As was pointed out in the paper mentioned, the investigation was defective in two respects. It was found that, in spite of the care which was taken to exclude mercury vapor from the apparatus, some of this vapor was undoubtedly present. This no doubt was due to the fact that the whole apparatus had to be maintained at a high temperature for long periods to insure drying, and thus the presence of the least speck of liquid mercury would cause, when evaporation took place, the diffusion of comparatively large quantities of the vapor through the apparatus. Again, the logarithmic decrement due to the friction in the suspending fibre was not determined directly by experiment, and in the discussion of the results obtained its value was calculated.

---

[1] Proc. Am. Acad., 42, 6 (1906).

[2] See p. 129 of that paper.

The details of the method since used to exclude the mercury vapor and to determine the decrement due to friction in the fibre will appear later. Meanwhile a summary of what has been accomplished is given here.

First, the decrement due to the friction in the suspending fibre of the viscosity apparatus has been determined experimentally.

Second, mercury vapor has been excluded to such a degree that, even when the whole apparatus, in which the presence of the vapor would be objectionable, was kept at a temperature of 150° C., the mercury lines were absent from the spectrum of the gas enclosed.

Third, the value of the decrement has been obtained for hydrogen over a range of pressures extending from atmospheric pressure to 0.000016 mm. as indicated by the McLeod gauge.

Fourth, an equation relating pressure to decrement has been obtained which applies well at all pressures below 0.1 mm. as far as pressures have been measured. The equation, above mentioned, is of the form of Sutherland's equation given tentatively in the former paper. It is

$$\left(\frac{k}{l-\mu}-1\right)p=c.$$

In this equation k and c are constants to be determined from the observations; l is the decrement due to whatever friction there is in the gas under examination and to the friction in the fibre; p is pressure; μ is the decrement due to the friction in the fibre. Its value has been measured directly. The significance of the two slightly differing values of μ, namely, $\mu = 0.000020$ and $\mu = 0.000022$, which are found in the following table, will appear later when the measurement is discussed in detail. The first column of the table contains a series of values of the decrement for hydrogen, each of which corresponds to a definite pressure in the gas. The various values of the pressure are given in the second column. The first three of them were obtained from a manometer. Those which are marked thus,*, were obtained from measurements made with the McLeod gauge, while the others were obtained from a curve plotted from the directly observed values of the decrement and pressure. From two values of p, the corresponding values of l, and the value of μ, there are obtained two equations for the determination of the constants k and c in the above equation. These determined, it is clear that from any value of l, within the range

indicated above, the corresponding value of p can be obtained from the formula by a simple calculation. The numbers thus obtained for the various values of l are given in the third and fourth columns.

It would, therefore, seem highly probable that so far as hydrogen is concerned the McLeod gauge can be relied upon for pressures as low as the lowest used, and which are recorded in Table I; and that, in the case of hydrogen, the measurement of friction can be used as a convenient and accurate method of measuring pressure, provided care is taken to exclude mercury vapor. This matter will be discussed at length later.

The details of the methods used to overcome the difficulties named above follow:

Measurement of Decrement due to the Friction in the Fibre.

Referring to Figure 1 it will be seen that the tube C is inserted in such a position that nothing can pass to the viscosity apparatus from the McLeod gauge, B, or from the pump, which is connected to D, without passing through it. This tube, C, therefore, replaces the tubes of sulphur and silver whose purpose was explained in the earlier paper. C is filled with granular charcoal, and is so arranged that either a cylindrical electrical heater or a long Dewar vessel can enclose it. When C had been placed in position and sealed in place, the whole apparatus was exhausted through D by means of the mechanical pump, and then dry air was allowed to pass in through an opening placed near the pump. The exhaustion was again performed and the admission of dry air repeated. This exhaustion and admission of air were carried out alternately many times for the purpose of removing the comparatively large quantities of moisture which had been formed in the vessel during the process of making the various joints in the construction of the apparatus. When it was certain that the whole apparatus had been made fairly dry, the cylindrical electric heater was placed about the tube C, and while the exhaustion proceeded the tube was raised to a temperature of about 150° C., to hasten the removal of the gas present in large quantities in the pores of the charcoal at atmospheric pressure, and which separates from the charcoal rather slowly under reduced pressure if the temperature is kept low. When the mercury pump had been used to secure a fairly high vacuum the other parts of the apparatus, viz., the McLeod gauge, the viscosity apparatus, and the connecting tubes were heated to about 150° C., for the purpose of removing from the glass the occluded gases. After the pumping had proceeded for some time under these conditions, the heater was re-

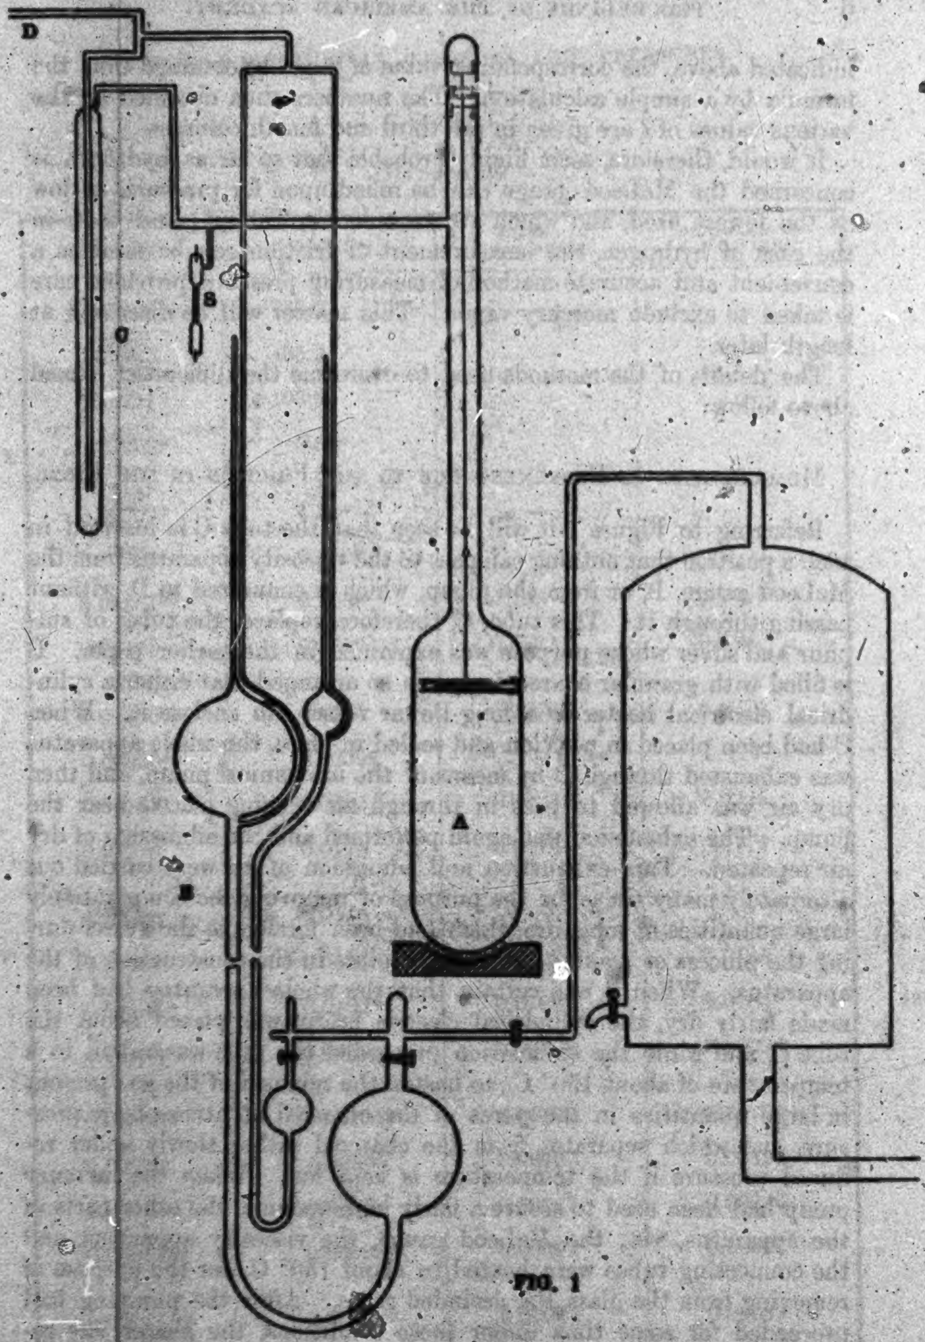

FIG. 1

moved from C and the Dewar vessel containing liquid air[3] was substituted for it, and the other part of the apparatus was allowed to cool down. The charcoal was allowed to absorb what it would at the temperature of the liquid air. Altogether the liquid air was kept surrounding the charcoal for about eighty hours, and from time to time during this interval a measurement of the decrement, l, was made. At first the diminution in the value of the decrement was fairly rapid, but after the first day the change was very slow. This, no doubt, was due in part to the slow passage of the gas towards the charcoal through the somewhat extended form of the apparatus. It was, also, probably due to the fact, which was noted later in the investigation, that at a given stage of exhaustion the raising of the free surface of the liquid air in the Dewar vessel surrounding C invariably produced a very appreciable diminution in the gas pressure in the apparatus, and the lowering of the free surface as the evaporation of the liquid air proceeded resulted in a distinct rise in the gas pressure. It is to be understood that the free surface was never allowed to fall as low as the top of the tube C, so that all of the charcoal was always below the free surface of the liquid air.

The following results show how the decrement changed with the time in the final forty-eight hours :

May 29,	12 M. to 2: 53 A. M.	Decrement 0.000051
	7: 15 P. M. to 8: 58	0.000037
	10: 53 P. M. to 1: 36 A. M. (May 30)	0.000031
May 30,	1: 36 A. M. to 4: 48	0.000028
	11: 11 A. M. to 2: 06 P. M.	0.000037*
	2: 06 P. M. to 5: 27	0.000024*
	5: 27 P. M. to 8: 21	0.000028*
	8: 21 P. M. to 11: 49	0.000022

The smallest value of the decrement obtained was 0.000022, and this could be measured moderately well. Its error cannot, I think, be as much as ten per cent. Of course, it is clear that the true value of the decrement due to the friction in the fibre is somewhat less than this, for there is still, doubtless, some gas left to offer resistance to the moving disk, so that the number to be used for μ in the above equation should be somewhat smaller than 0.000022. I have ventured to make use of the value 0.000020 as the true value to which the decrement will approach as the exhaustion is pushed higher and higher. It will be seen from Table I that the calculations are carried through not only with this value, but also with the actually measured value 0.000022. This is done simply to show what effect such a change in the value of μ has on the series of results obtained.

---

[3] The liquid air used in this investigation was obtained at the Chemical Laboratory, Harvard University.

* These were taken in the afternoon when there is considerable jarring of the apparatus and are probably not so accurate as the others.

It may be of interest to state that, at the stage of exhaustion when $\mu = 0.000022$ was obtained, the McLeod gauge indicated a pressure certainly less than 0.000001mm. It is, to be sure, of little value to give the measurement of a pressure by the gauge where a column of mercury a fraction of a millimeter high requires to be measured, and especially is this true where the tube containing the mercury has been heated and cooled repeatedly. The mercury has a habit of sticking to the glass to such an extent that pressure measurements under the conditions mentioned are surely not reliable. The value of the pressure given above, then, only indicates the order of magnitude of the pressure. Though the factor of the gauge used was 95813, yet it was quite inadequate to measure the pressure of the gas in the vessel.

REMOVAL OF WATER VAPOR AND MERCURY VAPOR FROM THE HYDROGEN IN THE VISCOSITY APPARATUS.

For this purpose it was necessary to make arrangements by which no vapor should be carried into the apparatus with the entering gas, and also all the vapor which was already in the apparatus might be taken out. The following arrangement was finally adopted, Figure 2. E is a U tube of small bore, and bent so that it may enter the long Dewar vessel already mentioned. For reasons which will appear later it was found necessary for the remainder of the investigation to replace the tube C, Figure 1, by this tube E. F is a tube leading from the gas generator. It enters G, which is similar to C of Figure 1. It can be surrounded by a heater or a Dewar vessel as circumstances may require. A connecting tube leads from G to a point on the tube H, which connects E to the viscosity apparatus A, Figure 1. I leads to the pump and McLeod gauge. Anything which proceeds from the pump or McLeod gauge towards the viscosity apparatus must pass through E. Moreover, the gas entering from the generator will, with the given arrangement, retard the diffusion of mercury vapor from the pump and gauge towards the viscosity apparatus. If there is no vapor entering with the gas, there can be none entering the viscosity apparatus without passing through E, and, since throughout the experiment this tube was kept surrounded by the liquid air, the pressure of the vapor due to diffusion from the mercury in the pump or gauge could never exceed the vapor pressure of mercury at the temperature of the liquid air. The tube G, when surrounded with the liquid air, was sufficient safeguard against the entrance of water vapor with the gas.

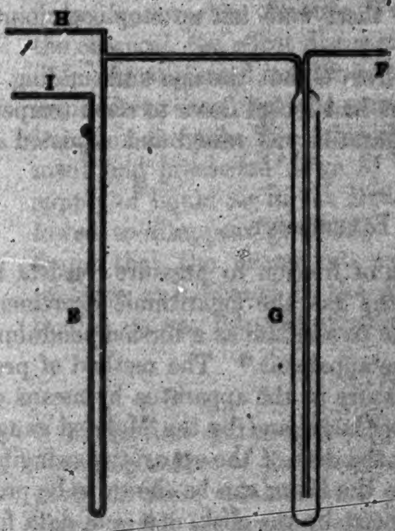

FIG. 2

The method of removing all water vapor and mercury vapor already in the apparatus beyond the tube E was that of repeated exhaustion and filling with the gas to be experimented with, the whole apparatus meanwhile being kept at a high temperature.*

At the first exhaustion, when the pressure had been reduced to a few centimeters of mercury, the tube G was surrounded by the electric heater, and the heat was applied to the oven in which the viscosity apparatus is placed. Practically the whole apparatus, except the gas generator, was kept hot while the pumping proceeded. After a fair vacuum was reached the pump was stopped and the hydrogen from the generator was allowed to enter very slowly, passing first over phosphoric pentoxide, and then over spongy platinum, heated in a combustion tube, before entering the tube G. This filling process was followed by another exhaustion under the same conditions. After the apparatus had been exhausted and filled a number of times in this way, when it seemed certain that the apparatus and the pores of the charcoal were filled with fairly pure hydrogen, the heater was removed from G, and the vessel containing the liquid air substituted for it. The same process of alternately exhausting and filling was continued, great care being taken in filling to allow the hydrogen to pass very slowly so that the drying process might be complete. Keeping the apparatus at a temperature of about 150° C. served to promote the evaporation of the mercury, which in all probability adhered to the inner glass surfaces. Comparatively large quantities of pure dry hydrogen were allowed to pass into the vessel and were then taken out. Each exhaustion would assuredly sweep out some vapor if it was present.

---

* The suspended disk was, of course, lowered before this operation began.

It would naturally collect at E. We shall have evidence as to this later. After some days of incessant work the expected result was attained, as the character of the spectrum, obtained from the spectrum tube, S, showed. Even when the temperature of the viscosity apparatus was 150° C. the mercury lines were absent. The apparatus was then very slowly filled with hydrogen. The glass tube connecting G and H was then sealed off so that there were left no stop-cock joints to give trouble by leaking.

The Dewar vessel was removed from G, but the one surrounding E still remained. After the apparatus had cooled down to room temperature the disk of the viscosity apparatus was raised and adjusted as described in the former paper.[5]

Method of Experiment.

The investigation of the relation of friction to pressure consists in measuring, for a given density of the gas, the logarithmic decrement of the suspended disk which is made to oscillate as a torsion pendulum between the two fixed plates of the apparatus.[6] The method of procedure was to measure the gas pressure in the apparatus by means of a manometer when the pressure was large, and by the McLeod gauge when it was small, and then to set the disk of the apparatus swinging and measure the decrement. Since the latter can be shown to be proportional to the resistance experienced by the disk, one gets data for the determination of the relation between friction and pressure.

It may be of interest to state here that in the first arrangement of the apparatus for the determination of the above relation instead of the simple bent tube E, a tube containing charcoal, similar to the tube C, was used. With this arrangement the mercury vapor was removed, but when observations on the decrement at different pressures were undertaken a difficulty presented itself. Although all of the tube containing the charcoal was immersed in the liquid air, the surface of which was always several inches above the top of the charcoal, yet it was found impossible to obtain a steady condition. As the evaporation of the liquid air proceeded, sufficient gas was given off from the charcoal to produce a large increase in pressure; as much as thirty per cent was observed. When a fresh supply of the liquid air was added the pressure diminished again. The difficulty became more serious as the pressure at which the observations were made became smaller.

The phenomenon was probably due to the fact that the fresh supply of liquid air was richer in nitrogen than it was after the process of boiling had proceeded for some hours. The nitrogen is the more volatile, and so the boiling will proceed more vigorously just after a fresh supply of air has been added than at any other time. Consequently, the temperature of the boiling liquid will be lower at first than it is later, and the charcoal will thus absorb better at each addition of liquid air to the Dewar vessel. The charcoal is necessary for the phenomenon, for when the tube E was substituting for the tube containing the charcoal, the effect disappeared, or became inappreciable.

---

[5] See pp. 133, 134.

[6] See pp. 124, 125 of former paper.

It was suggested earlier in the paper that there would be adduced evidence to show that the mercury driven out from the apparatus collected in the tube E. After the measurement of pressure and decrement had proceeded down to the least value given in the table, the supply of liquid air in the Dewar vessel in which E was placed was allowed to disappear gradually. As the evaporation proceeded, it was found that the decrement increased much more rapidly than the pressure as indicated by the McLeod gauge, showing that vapor was finding its way into the apparatus.

RESULTS.

In the first and second columns of Table I are contained the corresponding values of the decrement and pressure. Not all the numbers given in these columns were obtained by actual measurement. Only those which are marked with an asterisk were obtained in this way. The others were obtained as follows: A curve was plotted using the values of the pressure which were measured as abscissas and the corresponding values of the decrement as ordinates. This curve was drawn on such a scale that the value of the decrement, corresponding to any arbitrarily chosen pressure, could be obtained from the curve as accurately as it could be measured by the apparatus. The unmarked numbers in the first two columns were obtained by choosing arbitrarily a pressure and reading off from the curve the corresponding value of the decrement. In no case has this procedure involved an extrapolation.

After failing to obtain an analytical expression for the relation between the logarithmic decrement and the pressure which would be applicable over the whole range extending from very small pressures right up to atmospheric pressure, it was decided to find, if possible, an expression which would be applicable up to a certain pressure within the range for which it is known that the McLeod gauge measurements are quite reliable. Rayleigh[7] has shown that Boyle's Law holds down to 0.01mm. of mercury, and Baly and Ramsay[8] found the McLeod gauge measurements reliable for hydrogen. Recently Scheel and Heuse* have applied a membrane manometer, devised by them, to test Boyle's Law, and McLeod gauge measurements for air, and they state that they find both valid down to about 0.0001 mm., provided proper care is taken in drying the gas.

---

[7] Phil. Trans., 196 (1901).

[8] Phil. Mag., 38 (1894).

An examination of the results at pressures less than 0.1 mm. showed that the equation given above, viz.:

$$\left(\frac{k}{l-\mu}-1\right)p=c,$$

served the purpose exceedingly well, if the experimentally determined value of μ given above was used, and if the constants c and k were determined by means of values of p between 0.1 mm. and 0.01 mm. of mercury, and the corresponding values of l.

The pressures chosen for the determination of these constants were 0.0239 mm. and 0.0150 mm., the former of these being a pressure actually measured by the gauge, while the latter was chosen arbitrarily. The measurement of l corresponding to the former was 0.00936, while the value of l corresponding to the latter was 0.00620, and was obtained from the curve as described above. The values of the constants calculated from the above data are

$$c=0.1491$$
$$k=0.0676.$$

The equation now takes the form

$$\left(\frac{0.0676}{l-0.000020}-1\right)p=0.1491.$$

How well the equation gives the relation existing between p and l can be seen by a comparison of the numbers in the second and third columns of the table. A number in the third column is obtained by choosing a value of l from the first column, inserting it in the equation and deducing the value of p, which is then placed in the third column in the same horizontal row as the chosen value of l. It will be seen that the various numbers in this column agree very well with the corresponding numbers in the second column, except at the very lowest pressure, 0.000016 mm. used, when the difference is about twenty-five per cent.

---

* Verhandl. d. Deutsch. Physikal. Gesellsch., 11, 1 (1909).

If instead of using the value 0.000020 for μ, we make use of 0.000022, which was the smallest value of the decrement actually measured, the values of c and k are

$$c = 0.1494$$
$$k = 0.0677$$

and the fourth column gives the values of p calculated, in the way described, from the equation with these values for the constants instead of those used in the preceding case. This calculation is carried out to call attention to the magnitude of the change produced by a slight change in the value of the constant, μ, which is subject to some uncertainty, as has been shown. It will be seen that it is only where the decrement, l, is very small that the difference between the two results is appreciable. The smallest value of p in the fourth column is nearer to the corresponding value of p, measured by the McLeod gauge; but the measured value is subject to an inaccuracy about as great as the difference between the measured and calculated values of p.

The results given above make it highly probable that the measurements of pressure by the McLeod gauge are reliable in the case of pure, dry hydrogen for pressures as low as the smallest pressure recorded in the table.

It is to be observed that for pressures below, say, 0.01 mm. of mercury the friction with which we have to do is largely external friction, and this is proportional to the density of the gas and the mean molecular speed. The friction, and, therefore, the decrement, corresponding to a given pressure will be smaller for hydrogen than for, say, oxygen, or mercury vapor. In the case of mercury vapor the decrement at a given low pressure ought to be about ten times as great as it is for hydrogen at the same pressure, since the molecular weight of mercury is about one hundred times that of hydrogen, while the mean molecular speed is about one-tenth as great as it is for hydrogen.

To be sure it does not follow that the decrement of a mixture of hydrogen and mercury vapor, in such proportions that the partial pressures of the two are the same, is simply the sum of the two decrements obtained when the gas and vapor are separate. If one accepts the expression deduced by Meyer[10] for the external friction of a gas, and applies the same method in considering external friction of mixtures as he does in dealing with the internal friction of mixtures, he will be able better to understand how the external friction of a mixture of

---

[10] Kinetic Theory of Gases, p. 210 (Eng. Trans.).

[illegible]s depends upon the proportion in which the gases are mixed. [illegible]yer shows that the coefficient of external friction is given by

$$\tfrac{1}{4}\beta m N \Omega,$$

where m is the molecular weight of the gas; N is the number of molecules per unit volume; Ω is the mean molecular speed; and β is a constant depending upon the solid surface. He gives some experimental evidence to show that β is independent of the gas.

In the case of a mixture of gases where there are N_1 molecules of one kind and N_2 molecules of another, in each unit volume we have, if N is the total number of molecules in the unit volume,

$$N = N_1 + N_2$$

and the mean molecular weight is given by

$$m = \frac{N_1 m_1 + N_2 m_2}{N}$$

where m_1 and m_2 are the molecular weights of the two gases mixed.

Since the temperatures of the two gases are the same,

$$m_1 \Omega_1^2 = m_2 \Omega_2^2 = m \Omega^2.$$

Therefore,

$$m\Omega = m_1 \Omega_1 \sqrt{\frac{N_1}{N} + \frac{m_2}{m_1} \cdot \frac{N_2}{N}}.$$

If Boyle's Law holds, which seems a fair inference from the results given above, then we may write

$$m\Omega = m_1 \Omega_1 \sqrt{\frac{p_1}{p} + \frac{m_2}{m_1} \cdot \frac{p_2}{p}},$$

where p_1 and p_2 are the partial pressures and p is the whole pressure under the given conditions. If β is independent of the nature of the gas it follows that the ratio of the external friction of the mixture to the external friction of the gas whose partial pressure is p_1, if it were in the vessel alone, is

$$\frac{N m \Omega}{N_1 m_1 \Omega_1} = \frac{N m_1 \Omega_1 \sqrt{\frac{p_1}{p} + \frac{m_2}{m_1} \cdot \frac{p_2}{p}}}{N_1 m_1 \Omega_1} = \frac{N}{N_1} \sqrt{\frac{p_1}{p} + \frac{m_2}{m_1} \cdot \frac{p_2}{p}}.$$

If the mixture is one of hydrogen and mercury vapor such that $p_1 = p_2$, the above ratio becomes about 14. This means that if the pressure is measured by the McLeod gauge, which takes no account of the mercury vapor, the friction of the mixture would be about fourteen times as much as it would be with the same hydrogen pressure as in this case, but with the mercury vapor absent. If $p_1 = 1000p_2$, the ratio is about 1.05, and if $p_1 = 10{,}000p_2$, it becomes about 1.005.

It might be urged with regard to the method described above for freeing the hydrogen from mercury vapor that the lowest pressure of vapor obtainable by the method used is the pressure of mercury vapor at the temperature of liquid air boiling at atmospheric pressure. This pressure at 0° C. is about 0.0005 mm., but what it is at the lower temperature mentioned can hardly even be conjectured. We have simply to fall back upon the spectroscopic test. The above discussion shows, however, that if this pressure is less than 0.001 of the pressure of the hydrogen it will not very seriously affect the results. If it is as low as 0.0001 of the hydrogen pressure, then the error in the observations will easily be greater than any error introduced in this way. Considering the lowest pressure reached, namely, 0.000016 mm., the vapor pressure of mercury at the temperature of liquid air, boiling under atmospheric pressure, would require to be as low as 0.000,000,016 in order that the ratio of the partial pressures should be 1:1000.

This case serves to show how important it may be to consider mercury vapor when we are dealing with these very low pressures. It indicates that, in all high vacua work where we are considering the properties of a particular gas, it is important that great care should be taken to exclude this vapor. The McLeod gauge, of course, takes no cognizance of it, and in fact serves to introduce the vapor where it is not wanted. In all cases where the vacuum is high, and it is desirable to know the pressure in the vessel, and yet keep the gas pure, it would be desirable to have a gauge which would not introduce any impurity.

If the inference made above as to the validity of the McLeod gauge measurements on gas pressure is allowed, then we can say that reliance may be placed upon the measurements of pressure from decrement measurements in the apparatus used in this investigation. This method need introduce no mercury vapor, but it takes account of all that is in the vessel. Moreover, a discussion similar to that used for mercury vapor will show that in the case of oxygen the decrement, corresponding to a certain gas pressure, will be about four times as great as it is in the case of hydrogen. In the case of oxygen, therefore, a pressure of 0.00001 mm. should be measured with an accuracy of from five to ten per cent. This would indicate an absolute error of less than 0.000,001 mm.

The investigation is now being extended to the case of oxygen and nitrogen. The data obtained by using these gases, besides showing whether their behavior is like that of hydrogen, should give some more information regarding the quantity, β, which enters the foregoing discussion.

[TRANSLATION]

A Contribution to the Knowledge of the Inertia of Moving Electrons.

[Beitrag zur Kenntnis der tragen Masse Bewegter Elektronen.]

By E. HUPKA

Annalen der Physik. Ser. 4 Vol. 31 (1910) p. 169.

[169]

The development which the Theory of Electricity and Magnetism has undergone since it was placed on an atomistic basis has led to a modification and a clearer understanding of various fundamental concepts from other fields of physics. In particular the concept of the inertia of matter has been broadened; the earlier electrodynamics admitted no functional dependence of inertia upon motion, whereas the newer electron-theories require the inertia of an electron to vary with its speed. Two of these theories are of especial interest because of their systematic structure; Abraham's theory of the rigid electron,[1] and the Lorentz-Einstein theory.[2] The difference between the two is best characterized by their relations to the Principle of Relativity. This principle states that the equations of motion have the same form in a coordinate-system at absolute rest as in a coordinate-system moving with uniform velocity relatively to the former one. The Abraham theory—we shall, like Planck, call it the "sphere-theory" for shortness—is incompatible with the principle of relativity; the Lorentz-Einstein theory—hereafter to be called the "relativity-theory"—makes this principle, together with a suitable [170] definition of time, the foundation of all its developments.

It is obvious that theories starting from such different viewpoints must lead to different conclusions about

phenomena involving motion, and these conclusions can be put to an experimental test and thus a decision between the two theories obtained. The best promise of success is offered by an investigation of the dependence of the mass of a moving electron on its speed; each theory predicting dependence but not the same law of dependence. W. Kaufmann, in his beautiful work on "The Constitution of the Electron",[3] demonstrated the existence of such a dependence by experiment. The data he gives cannot be brought into complete accord with either theory; the deviations from either exceed the magnitude of the experimental uncertainty as assigned by Kaufmann. From his measurements and those of H. Starke,[4] A. Bestelmeyer,[5] J. Classen[6] and others we may consider the fact of dependence of the inertia of an electron upon its speed as experimentally established. These experiments however did not form an adequate basis for criticizing the theories. Bucherer has recently[7] described experiments which support the relativity theory. Considering the importance of the question to the further development of the theories, a new test with different means should not be superfluous. Kaufmann and Bucherer worked with the β-rays of radium salts. The experiments here to be described (they were going on before Bucherer's article appeared)
[171] were performed with cathode rays of high speed. It is true that Starke's experiment, in which the discharge was produced by the applied potential alone, indicated that the range of velocities which could be thus attained would not be sufficiently wide to give a satisfactory accuracy; but the perfection to which modern methods of evacuation have been brought makes it possible to generate the cathode rays in some other way and then accelerate them by means of high static potentials, without involving a visible discharge and the associated complications. This was attained by producing a stream of electrons photo-electrically and bringing it

up to a great speed by means of high potential differences.

B. THE EXPERIMENTS

1. *Theory of the Experiments*

As the velocity of emission of the rays produced in this way amounts to only a few volts, according to the measurements of E. Ladenburg[8] and K. Markau,[9] and therefore can be regarded as infinitely small relatively to the final velocities attained, the equations given by Planck[10] may be used as the basis for these calculations. They are the same for both theories.

$$(1) \qquad E = \varepsilon P . 10^8 = q p - H;$$

$$(2) \qquad p = \varepsilon H \rho$$

E is the energy, H the kinetic potential of an electron moving with velocity q, ε is the elementary electrical charge in electro-magnetic units, P is the accelerating potential in volts, *H* the intensity of the field used for magnetic deflection, ρ the radius of curvature of the trajectory and $p = \delta H / \delta q$ the impulse-vector. The difference between the two theories is characterized by the

[172] following equations:

$$(3) \qquad H = -\frac{3}{4} \mu_0 c^2 \left[\frac{c^2 - q^2}{2 q c} \ln \left(\frac{c + q}{c - q} \right) - 1 \right]$$

for the sphere-theory

$$(4) \qquad H = - \mu_0 c^2 \left(\sqrt{1 - \frac{q^2}{c^2}} - 1 \right)$$

for the relativity- theory.

c is the velocity of light, μ_0 is the mass of the electron for $q = 0$. If we also take $\beta = q/c$ and $\eta_0 = \varepsilon / \mu_0$, we obtain from (1) and (3) or from (1) and (4):

(I) (5)

$$p = \frac{9.10^2.c}{4\,\eta_0}\left(\frac{1}{\beta}\ln\frac{1+\beta}{1-\beta} - 2\right)$$

for the sphere-theory.

(6)

$$p' = \frac{3.10^2.c}{\eta_0}\left(\frac{1}{\sqrt{1-\beta'^2}} - 1\right)$$

for the relativity-theory.

From $P = \mu q$ (μ is the inertia of the electron for velocity q) and the combination of equation (2) with (3) or (4), we obtain

(II) (7)

$$\frac{1}{c}\,\eta_0\, H\rho = \frac{3}{4}\,\frac{1}{\beta}\left(\frac{1+\beta^2}{2\beta}\ln\frac{1+\beta}{1-\beta} - 1\right)$$

for the sphere-theory.

(8)

$$\frac{1}{c}\,\eta_0\, H\rho = \frac{\beta'}{\sqrt{1-\beta'^2}}$$

for the relativity-theory.

The equations (I) contain only β, η_0, and some known constants; the equation (II) contain these and the quantities H and ρ, to be obtained by experiment, as well. We can assume a definite value for η_0, then determine the function β from η_0 and P, by means of (I). Insert this expression for β in (II) and see whether η_0 comes out constant in (II). If it comes out constant on either theory, that theory is the right one.

Another consideration will lead to the same equations. If as before, we designate by E the energy of the electron, using E for its value of velocity q, and E_0 for its value at the initial velocity q_0; by P and P_0 the corresponding potentials in volts; by e, the elementary electrical change in electrostatic units, by a the radius of the electron at rest, we obtain from the principle of conservation energy the following relation.

[173]

$$E - E_0 = \frac{e(P - P_0)}{300}. \tag{9}$$

In the sphere-theory the entire energy is electro-magnetic, therefore, if W is this energy,

$$E - E_0 = W - W_0.$$

But in case of a surface distribution of charge, we have:

$$W = \frac{e^2}{2a}\frac{1}{\beta}\ln\frac{1+\beta}{1-\beta}; \tag{10}$$

In the case of a volume distribution of charge, on the other hand

$$W = \frac{3\,e^2}{5a}\frac{1}{\beta}\ln\frac{1+\beta}{1-\beta}; \tag{11}$$

or, since:—

$$\frac{e^2}{a} = \frac{3}{2}\mu_0 c^2 \text{ for surface charge} \tag{12}$$

$$\frac{e^2}{a} = \frac{5}{4}\mu_0\, c^2 \text{ for volume charge.} \tag{13}$$

we get, irrespective the distribution of the charge,

$$\frac{P - P_0}{300} = \frac{3\mu_0\, c^2}{4e}\left(\frac{1}{\beta}\ln\frac{1+\beta}{1-\beta} - \frac{1}{\beta_0}\ln\frac{1+\beta_0}{1-\beta_0}\right). \tag{14}$$

In the relativity-theory we have in addition to the purely electro-magnetic energy W an inner potential energy L of the electron. The energy equation is as follows:—

$$W - W_0 + L - L_0 = e\left(\frac{P - P_0}{300}\right). \tag{15}$$

In the case of surface charge, we have:—

$$W = \frac{e^2}{2a\sqrt{1-\beta^2}}\left(1 + \frac{\beta^2}{3}\right). \tag{16}$$

$$L - L_0 = \frac{e^2}{6a}\left(\sqrt{1-\beta^2} - \sqrt{1-\beta_0{}^2}\right). \tag{17}$$

If these values are substituted in (15) we get:

(18)

$$\frac{P - P_0}{300} = \frac{e}{6a}\left(\frac{3 + \beta^2}{\sqrt{1 - \beta^2}} - \frac{3 + \beta_0{}^2}{\sqrt{1 - \beta_0{}^2}} + \sqrt{1 - \beta^2} - \sqrt{1 -}\right.$$

In the case of volume charge, the right hand side must be multiplied by $\frac{6}{5}$. By carrying out the substitutions (12) and (13), we obtain the following relation which [174] is independent of the mode of distribution of the charge:

(19)

$$\frac{P - P_0}{300} = \frac{\mu_0 c^2}{4e}\left(\frac{3 + \beta^2}{\sqrt{1 - \beta^2}} - \frac{3 + \beta_0{}^2}{\sqrt{1 - \beta_0{}^2}} + \sqrt{1 - \beta^2} - \sqrt{1}\right.$$

If we write

$$\frac{e}{\mu_0 c} = \frac{\varepsilon}{\mu_0} = \eta_0.$$

we obtain

$$(20) \quad P - P_0 = \frac{9.10^2 c}{4\,\eta_0}\left(\frac{1}{\beta}\ln\frac{1 + \beta}{1 - \beta} - \frac{1}{\beta_0}\ln\frac{1 + \beta_0}{1 - \beta_0}\right)$$

For the sphere-theory.

$$(21) \quad P - P_0 = \frac{3.10^2 c}{4\,\eta_0}\left(\frac{1}{\sqrt{1 - \beta^2}} - \frac{1}{\sqrt{1 - \beta_0{}^2}}\right)$$

for the relativity-theory.

and for small values of the initial velocity, exactly as in equations (5) and (6).

$$(22) \quad P = \frac{9.10^2 c}{4\,\eta_0}\left(\frac{1}{\beta}\ln\frac{1 + \beta}{1 - \beta} - 2\right)$$

the sphere-theory.

$$(23) \quad P' = \frac{3.10^2 c}{\eta_0}\left(\frac{1}{\sqrt{1 - \beta'^2}} - 1\right)$$

For the relativity theory.

Developed into series, these equations are:

$$(22\text{-a})\quad P = \frac{3.10^2 c}{2\,\eta_0}\left(\beta^2 + \frac{3}{5}\beta^4 + \ldots + \frac{3}{2n+1}\beta^{2n} + \ldots\right)$$

Sphere-theory,

(23-a)

$$P' = \frac{3.10^2 c}{\eta_0}\left(\frac{1}{2}\beta'^2 + \frac{3}{8}\beta'^4 + \ldots + (-1)^n\left(n - \frac{1}{2}\right)\beta'^{2n} + \ldots\right)$$

(for the relativity theory)

For small velocities we can be satisfied with the first term of the series. We then obtain, on both theories:

$$(24)\qquad P = P' = \frac{3.10^2.c}{2\,\eta_0}\beta^2.$$

In the former theory of electricity, and magnetism which did not recognize the dependence of. mass upon the velocity, this equation was regarded as valid for higher velocities as well.

It would be worth while to discuss these equations as Planck has already done in regard to what conclusions may be drawn, as to the quantitative difference [175] between the theories. A ray which has fallen through a given potential P has a certain energy E which is independent of the theory selected. Hence, we have the following equation:

$$(25)\qquad \frac{3}{2}\left(\frac{1}{2\beta}\ln\frac{1+\beta}{1-\beta} - 1\right) = \frac{1}{\sqrt{1-\beta'^2}} - 1.$$

The magnetic deviability is characterized by the reciprocal value $(1/c)\ \eta_0\ H_\rho$. From this it follows that:—

$$\beta' < \beta$$

$$\frac{\beta'}{\sqrt{1-\beta'^2}} > \frac{3}{4}\,\frac{1}{\beta}\left(\frac{1+\beta^2}{2\beta}\ln\frac{1+\beta}{1-\beta} - 1\right)$$

that is, a ray which has fallen through a given potential possesses according to the sphere theory a greater velocity and a greater magnetic deviability than according to the relativity-theory. The difference disappears in the cases of very small and very high potentials; a maximum is obtained, as Planck has shown for $P = 3.2\ 10^5$ Volt ($\beta = 0{,}834$). One-half the velocity of light is equivalent to a discharge potential of about 75,000 volts, on the sphere-theory and about 78,000 volts on the relativity-theory.[11)]

2. *The Experimental Details.*

A. Apparatus and Technique.

The idea suggested by these theories was realized by the arrangement shown in Figure No. 1. By light from a quartz mercury lamp L a stream of electrons was

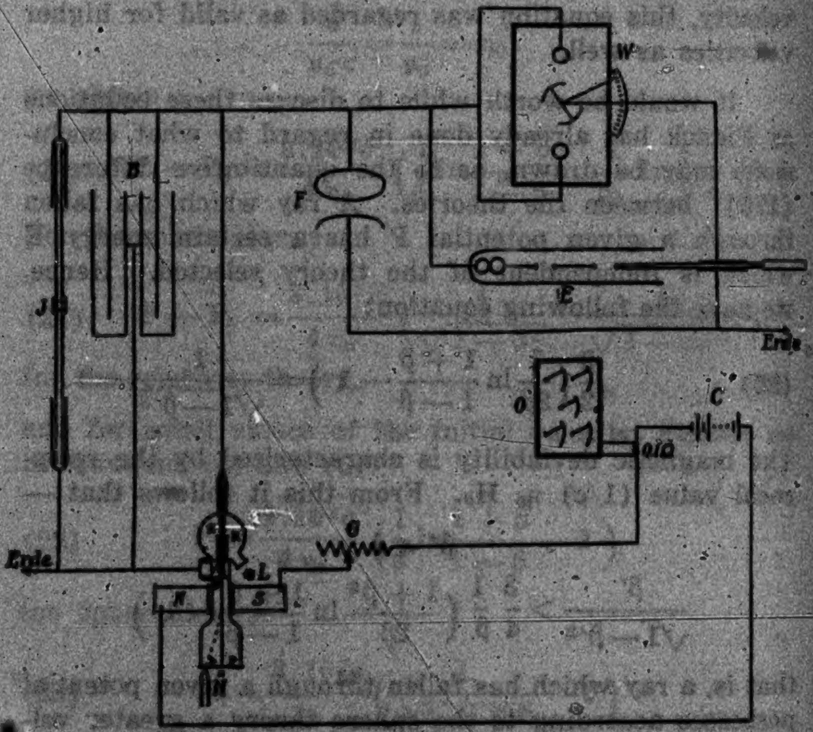

Fig. 1.

liberated from a copper cathode K in a discharge tube R which was evacuated to a high degree by means of coconut charcoal and liquid air. The beam, highly accelerated by a field applied between the cathode and the anode A, traversed the anode which had the shape of a diaphragm [i.e., a hole in a screen]—with constant speed, and then a second diaphragm D over which were stretched two crossed Wollaston wires; the beam cast the shadow of this cross upon a phosphorescent screen P at the end of the tube. A pair of coils NS was placed with its axis perpendicular to the axis of the tube behind the second diaphragm; when a current (to be called the magnetic current) was sent through these coils the beam was deflected and the shadow of the cross displaced from a to b. To escape disturbances from the earth's magnetic field the discharge tube was screwed into a perfectly iron-free support parallel to the magnetic meridian; the deflections were in the vertical plane.

A scheme for producing high static potential differences and measuring them very accurately has been [177] worked out by Müller[12] in this Institute and has been briefly described. This method was used in the present case. The cathode was connected with the negative pole of a battery of Leyden jars, which was charged

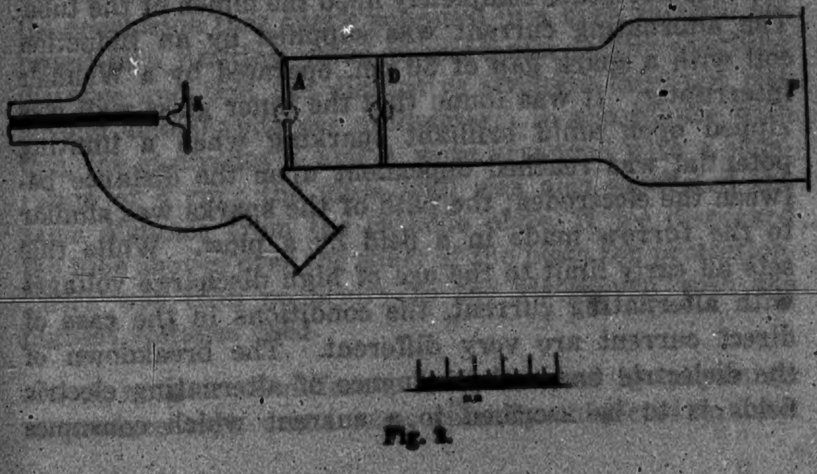

Fig. 1.

by an electrostatic machine J constructed for high potential differences and having plates of a diameter of 90 cm.; the positive pole and the anode were earthed through a lightning-conductor. The P.D. could be regulated by means of a subdivided spark-gap (cf. 12); the readings were taken with a bifilar torsion-balance with pointer and scale, calibrated from observed sparking-distance by Müller's method.

The magnetic current was taken from a 20-volt storage-battery C, regulated by a sliding rheostat and measured by a compensator across a standard resistance of 0.1 ohm (calibrated by the Physikalisch Technische Reichsanstalt) immersed in paraffin-oil. The displacement of the shadow was observed with a microscope magnifying about 16 fold.

The opinion is often expressed, based on experience with high frequency alternating currents, that even in the best vacuum the use of high voltages is out of the question owing to the danger of breaking the glass walls. I thoroughly confirm this information from my [178] own experience as far as alternating current is concerned. At first I expect to obtain higher discharge potentials by increasing the cathode drop and for this purpose I put insulated electrodes between the cathodes and anode. This was not successful unless these intermediate electrodes completely filled the lumen of the tube. The alternating current was supplied by an induction coil with a spark gap of 30 cm. operated by a Wehnelt interrupter. It was found that the inner glass wall was ripped open amid brilliant sparking when a limiting potential was reached dependent upon the distance between the electrodes; the path of the sparks was similar to the furrow made in a field by a plow. While this sets an early limit to the use of high discharge voltages with alternating current, the conditions in the case of direct current are very different. The breakdown of the dielectric under the influence of alternating electric fields is to be ascribed to a current which consumes energy. But the value of the resistance deduced from alternating current losses, corresponding to this current, is, as experiments show, very small in comparison with the direct current resistance. For a telephone cable[13] direct current measurement gives an insulation resistance of 1,000 megohms and an a.c. resistance of about 100,000 ohms; a paper condenser[14] with a capacity of 2 microfarads has an insulation resistance of seventy million ohms and an a.c. resistance of about 2,500 ohms on alternating current of 800 to 900 cycles (talking currents). We have at present no satisfactory explanation for these facts. A part of the loss is perhaps due to molecular friction caused by the alternating polarization of the dielectric; the result would be for the electric in- [179] duction to lag behind electric field. The dielectric loss would then be analogous to the loss by hysteresis in magnetic substances.[15] According to the recent investigations of E. V. Schweidler,[16] this assumption does not afford a quantitative explanation. Perhaps a current due to conduction is involved, possibly electrolytic in nature. In any case, it is certain that with direct current, there will be less strain to the dielectric, in this instance to the glass wall of the discharge tube, than in the case of alternating current.

Experiments were performed by Madelung[17] on the disruptive strength of high vacua which led him to the conclusion that spark potential in a high vacuum approaches a limiting value proportional to the sparking distance and that the disruptive strength does not rise beyond 40,000 volts per millimeter. In accordance with this, the electrodes K and A were arranged with a separation of 4 cm.; the glass wall was also separated the same distance from the cathode plate, if we disregard the tube shoved over the shaft of the plate for protection. There was then no injury to the glass even with the highest voltages used.

A number of different methods used by physicists to produce high vacua were recently subjected to trial by Heuse and Scheel[18] in the Physikalisch-Technischen Reichsanstalt. As a result of these experiments, it may be stated that the maximum degree of evacuation can be reached only when coconut charcoal and liquid air are used. The lowest pressures (0.000007 millimeters) were obtained in about two hours after a preliminary evacuation with a Gaede pump. I have also made ex- [180] periments with the process of calcium vaporization suggested by Soddy.[19] In one case a calcium pencil connected in the circuit by a loose contact was vaporized by direct short-circuiting and formation of an arc. Another time pieces of calcium, the size of peas, were put into a porcelain tube cemented to the vessel to be evacuated and closed at the end; this was carefully heated to a red heat by the flame of a blower. The degrees of evacuation obtained in this manner were not inconsiderable; for instance, a vessel of about ½ liter capacity was reduced from a water jet vacuum to a hard X-ray vacuum at the moment of vaporization. For the present purpose, however, this method was not adequate. The charcoal and liquid air method, therefore, alone was used. To the side of the enlarged part (containing the phosphorescent screen) of the discharge tube, carrying the phosphorescent screen, was soldered a container about 15 cm. long and 2 cm. wide which was filled half full with coconut charcoal. A wad of glass wool was used to prevent the carbon particles from falling into the discharge tube. The apparatus was so connected with the mercury pump, that the carbon tube was horizontal in position. A sheet of metal about 8 cm. wide was slipped over it and was heated by a multiple-burner from below to a temperature near the melting point of glass.

Special care was taken in preparing the carbon. The shells of a coconut were cut up to the size of peas and carbonized by dry distillation in a metal box with a perforated cover and with a reduced amount of air. The process could be regarded as finished when the clouds of yellowish white smoke disappeared. The product formed in this way had a greyish black appearance and matt fracture; on account of the amount of tar it contained it could not be used for evacuation; it had to be glowed in a glass tube under a vacuum. This was done by a water jet pump, the tube being heated about 6 to 7 hours to a temperature of about 400 degrees. This gave the carbon a deep black color and the fracture was mirror-like and conchoidal. This preparation also could [181] not be used until after the remaining nyrocarbons had been removed by continuous evacuation and heating for several days in a high vacuum (mercury pump); the two phosphorus pentoxide tubes attached for drying took on a brown color and had to be changed many times. The definitive experiments could not be started until the drying-material remained white. It was found desirable not to keep the mercury pump continuously in operation but to work intermittently; at first it was evacuated until the glass wall of a Geissler tube, serving as a vacuum-indicator and opening into the container, displayed green fluorescence; the pump was then stopped and I waited until the cathode dark space was only one millimeter wide owing to the giving off of gas from the carbon; then the pump was set in operation again and was evacuated until the fluorescence began; the pump was again stopped until the cathode dark space had been reduced to one millimeter, and so on. Possibly, there is a certain value of the pressure-gradient favorable to the rapid emptying of the container while at lower pressures the friction of the gas on the walls acts as a hindrance to evacuation. In any case, the process still occupied from six to eight hours. Finally, when a spark gap of 3 cm. in parallel with the indicator operated with the carbon heated to the highest possible degree, the container was separated from the pump. A method of evacuation with coconut charcoal and liquid air, which is possibly promising, was used at about the same time independently by Heuse and Scheel, by Regener in the Physics Institute, and by myself; a number of charcoal tubes are fused in series to the container to be evacuated, all the tubes are heated at the same time, while they are constantly being evacuated by the pump (a water jet pump will do); then one of the tubes is cooled to room temperature; this absorbs the gas given off by the other tubes; the cooled tube is sealed off from the container, and then the next carbon tube is cooled, melted off from the container, etc., until only one tube [182] is left. If this is now placed in liquid air, the highest attainable vacuum is obtained.

According to experiments of E. Tieffenbach in this Institute, when charcoal is dipped into liquid air there is a fairly rapid fall of temperature down to about 100° c, after which the further decline is extremely slow. Hence after applying the liquid air to the charcoal we waited 3 or 4 hours before beginning with the measurements, mean-while constantly refilling to replace the evaporated air.

Vacua made in this way stood up under about 90,000 volts without a discharge taking place of itself. Under these conditions effects are observed which are very remarkable. In spite of a discharge potential which in air at atmospheric pressure corresponds to a gap of 8 cm. between 5 cm. balls, the eye does not perceive the slightest light inside the tube. If ultra-violet light is allowed to fall on the cathode a bright spot appears on the phosphorescent screen. If the source of radiation is screened off by glass plates, this phenomenon disappears. If the vacuum is not high enough (this was especially the case after the discharge tube had been stored for some time at atmospheric pressure) sparks occurred in the vacuum at the higher voltages. These were brilliant and made almost no noise; they were able to cause short-circuits, by the excitation of oscillations, in the wiring in rooms twenty meters and more away. Studied with the hand spectroscope they displaced in particular the spectrum of aluminium, with the exception of one yellow line. If the vacuum is harder and the sparking, therefore, less frequent, the glass becomes fluorescent before discharge. Reichenheim[20] recently made a study of the fluorescence-colors which the glass displays under the action of cathode rays, but found that [183] instead of the ordinary yellowish green color the fluorescence displayed at times a marked blue. Reichenheim ascribed this to the occurrence of secondary rays. We observed both colors in our experiments, green fluorescence in a relatively poor vacuum and blue in a good vacuum.[21)] Perhaps this is due to the fact that the blue color is the actual fluorescence due to the glass, whereas the green is due to adhering films of gas.

A circular sky-blue spot of phosphorescence appeared on the screen with an outline, which was very sharp even when enlarged with the microscope. Its intrinsic brightness was very notable, considering the small number of electrodes released by the photo-electric effect; in a darkened room it could be clearly observed at a distance of several meters. To prevent disturbing charges on the screen (the conductivity of the substance was usually sufficient for this) a fine-meshed wire net was stretched over the screen and grounded.

The source of ultra-violet light was a quartz mercury vapor high-pressure 220-volt lamp from the Heraceus Company, and this was operated on 130 to 140 volts terminal voltages and about 3.5 ampere from the city supply, with a suitable ballast resistance.

This was enclosed in a zinc box to keep the light out of the room; a beam of the light passed through a tube applied at an angle of 45°, and through a quartz window into the discharge-tube. [It is not clear whether the tube was attached to the box or to the discharge-tube, but probably the latter—K. K. D.] The wires leading to the lamp were so arranged as not to affect the magnetic field in the discharge-tube, and when a similarly [184] placed current was suddenly raised from 2 to 5 amperes no displacement of the phosphorescent spot could be detected.

The quartz window was a plate 4 cm. in diameter from the Busch Company in Rathenow and it was out perpendicularly to the optical axis. White cement No. 849-A from the Liliendahl Company in Neudietendorf was used for cementing it to the ground edge of the glass tube. This material has proved extraordinarily good as a vacuum cement; it is to be preferred to ordinary red sealing wax because of its low melting point, its fine-grainedness and especially its toughness. When sealing-wax is used it eventually begins to leak through microscopic cracks and breaks, produced by mechanical jarrings or by non-uniform temperatures and due to the brittleness of the substance. If we wash the shellac out with alcohol, we obtain a material which because of its calcium content gives a beautiful sky-blue phosphorescence under the influence of cathode rays.

The cathode is made of copper since copper is the most active substance photo-electrically next to carbon; a sufficiently high vacuum could not be expected with carbon (lampblack). Aluminium was chosen for the diaphragms because it gives off the least gas in a vacuum. Unfortunately, I could not obtain English aluminium which contains occluded gases to only a small degree,[22] but a few sparks produced in a high vacuum by very high voltages removed sufficient of the gas from the electrodes.

To obtain a suitable phosphorescent material, I made unsuccessful experiments for a long time on the products of the various firms; finally, I found that Kahlbaum's "Sidotblende" can be used. The white powder was stirred up into a milky paste with a 30 per cent sodium water glass solution in a porcelain crucible, was [185] applied evenly to a heated mirror-glass plate with a marten hair brush and finally the coating was dried as rapidly as possible over a flame at a given distance away from it. The screen was then cemented to the end of the tube in the same way as the quartz plate. The two cemented joints were carefully screened for protection against injury from ultra-violet light or cathode rays.

The magnet coils HS each had 400 windings of 1-millimeter enameled wire which was wound in three layers on two boxwood cylinders with a diameter of 6 centimeters and a length of fifteen centimeters. The whole apparatus, discharge tube and coils, was supported by wooden frames strengthened with rods at the side; a number of brass screws and clamps held it in place. Two wooden clamps held the frame to an oak table. Blows with a heavy hammer 5 centimeters away from one leg of the experiment table on the stone floor did not cause the phosphorescent spot to be displaced at all.

To obtain and measure the accelerating potentials we made use of a part of Müller's apparatus. In working with this apparatus we used the same care as did Müller; especially in regard to insulation were the previously approved precautions taken. I was very grateful for the advise of Müller in this matter.

Dish shaped electrodes, for which Müller's measurements are most accurate, were used for calibration. The delay in sparking was eliminated by using Röntgen rays. The X-ray tube with watercooled anticathode from the Gundelach Co. was operated by an induction coil with a spark gap of thirty centimeters and a Wehnelt interrupter. A Bamburg type of cathetometer was used to measure the separation between the electrodes. The positive pole of all parts of the high tension apparatus was connected, through three copper tapes two [186] centimeters wide, with a lightning conductor. The metal tapes were soldered to the lightning conductors at a point about three meters away from the ground. In this way alone was it possible to avoid the disturbances throughout the building (sparking from the gas or water faucets), resulting from earthing the system to the gas or water mains.

To regulate the magnetic current a ten ohm resistance was used and also a sliding rheostat of 2.5 ohms in series with it. A Raps compensator was used to measure the current. The standard cell of this apparatus was compared with a standard cell calibrated by the Physikalisch-Technische Reichsanstalt. The galvanometer, which served as a zero-instrument, had a resistance of 1,000 ohms and a sensitivity of $2.7 . 10^{-9}$ ampere per millimeter of deflection.

The reading microscope was provided with a micrometer thread; it was supported by a telescope base which was 1¼ meters in height.

The details in regard to the discharge tubes, especially the dimensions of the different parts may be obtained from figure No. 2.

B. The Measurements and Results.

The method of measurement used was a relative one. The absolute value of the deflections was not determined, but it was kept constant, when the potential difference between the electrodes was varied, by suitable regulation of the magnetic current, and this constancy was tested by the microscope. The experimental procedure was as follows: A given P.D. was established between cathode and diaphragm and at the same time the magnetic current J was adjusted to a given intensity; then the shadow of the crossed threads was brought in alignment with the micrometer-thread and the current and voltage were read. Then with the position of the microscope and the discharge tube unchanged, a new value was given the voltage, the magnetic current was changed correspondingly, and the voltage and current were again read at the moment when the micrometer-thread and the shadow coincided. In this way, are obtained directly the data necessary for the further
[187] calculations, viz., a series of corresponding values of P and J or of P and H, and these correspond to the same deflection a b of the bundle of cathode rays, and therefore, also to the same value of ρ.

The accuracy of the microscope readings was about 0.015 millimeter and the total deflection on a b was 15 to 30 millimeters. The greatest possible error in the determination of the potential was estimated at ± 80 volts. The greatest possible error in the measurement of the current was ± 0.5 Promille. Static charges inside the tube were not detected in any of the experiments employed in the computations. Charges of this kind make their presence known by irregular flickering displacements of the spot of phosphorescence in the microscope, before they are visible to the naked eye through the fluorescence of the glass.

In explanation of the table following, note that the quantity C in the last column was obtained by dividing equations (II) by the magnetic current J. For, if we set the magnetic field H equal to KJ,—K being a quantity which is constant throughout any one run—the left-hand members of equations (II) assume the form $\frac{1}{c} \eta_0 K J_\rho$; and dividing this by J_1 the quotient $\frac{1}{c} \eta_0 K_\rho$ will be found to be constant for whichever theory conforms to the facts. The values corresponding to the case of constant mass were obtained from equation (24). The value $\eta_0 = 1.77 \cdot 10^7$ found by Classen is the basis of the calculation of β from (I) or (24). The same value was obtained in Bucherer's[23)] measurements and recently by Wolz.[24)] The choice of a different value affects only the absolute value of C (β), without interfering with its general trend. Table X given at the end shows this very clearly; in this table of the value $\eta_0 = 1.77 \cdot 10^7$, we took $\eta_0 = 1.80 \cdot 10^7$.

[188]

[194]

The experiments are favorable to the relativity-theory. While the value of C (β) calculated from the relativity-theory varies very slightly about a constant average value, the corresponding C (β) calculated by the sphere-theory decreases at a nearly uniform rate with increasing voltage P. The amount of the decrease about six to twenty times as great as the average deviation of C (β), computed by the relativity-theory, from its mean. In accordance with a result obtained above theoretically, the values of β calculated by the sphere-theory are greater than the equivalent values by the relativity-theory. Very great deviations are obtained if a constant mass is assumed. In this case, the rays under a discharge potential of 250,000 volts would reach the velocity of light. The value C (β) which is inversely proportional to the magnetic deviability, comes out smaller by the sphere-theory than by the relativity-theory, as theory requires.

A graphical representation of the experiments (Tables I to X) is furnished by the curves in Figures No. 3 to No. 11. The curves for the hypothesis of constant mass are left out of the figures on account of lack of space. They also would show a practically straight line and would form an angle of about 70° with the horizontal. If the curves are extrapolated graphically by prolonging the curves in the direction of decreasing voltages, common points of intersection are reached in the neighborhood of zero potential.

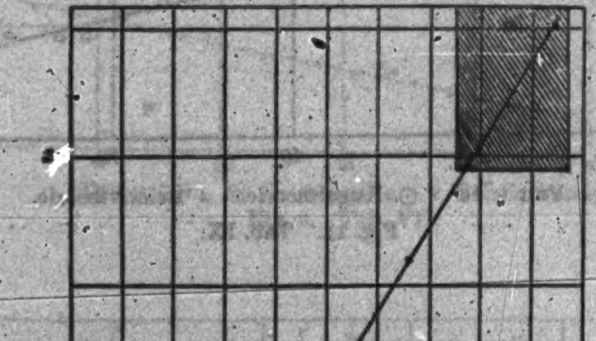
[195]

The velocities here obtained, 0.5 c and over, are the [198] greatest yet obtained by acceleration through electrostatic fields. Serious experimental difficulties stand in the way of producing decidedly larger accelerations by the application of higher potentials. This restriction on the attainable velocity makes very great exactitude in the potential measurements necessary. Were an error of 800 volts possible, in connection with a particular law of errors, the experimental results could be interpreted as favorable to the sphere theory. Therefore, it is of importance to discuss the accuracy of Müller's measurements. The accuracy of the absolute values of the spark potentials is not so important as the ratio of the individual values to one another since the multiplication of the absolute values by a factor nearly equal to unity has only a slight effect upon the results of the measurements given above. A table given

[199] by Müller (Dissertation, Berlin, 1908, page 70) offers a basis for a test of this kind. Müller there assembles the values which he obtained for the spark potential with a spark gap of 40 millimeters between practically plane surfaces; values which were obtained by comparison with the spark potentials at 10, 20 and 30 millimeters. For the sake of convenience, I will reproduce this table:

10 mm. gave for a gap of 40 mm.	103,200 volts 103,800 volts 104,100 volts
20 mm. gave for a gap of 40 mm.	103,800 volts
30 mm. gave for a gap of 40 mm.	104,100 volts



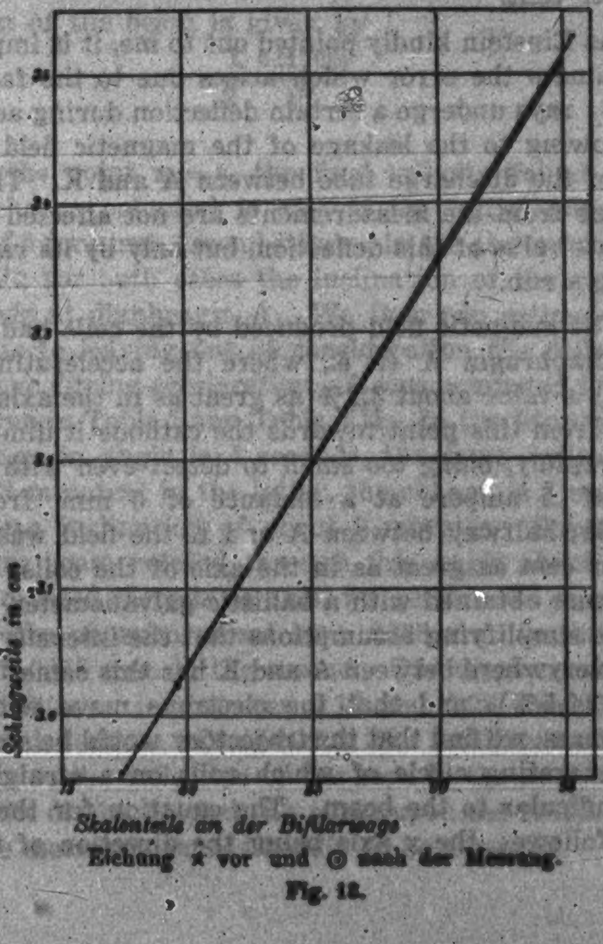
Eichung × vor und ⊙ nach den Messungen.

Fig. 12.

The average deviation of these final values from the average, 103,800 volts, is about 240 volts, that is, about ¼%. The various values were obtained on different days, whereas the calibrations given here occupied only a few hours. The following table of calibration and its graphical representation in Figures No. 12 and No. 13 gives a typical instance of calibration before and after a series of experiments:

(TABLE OF CALIBRATION)[25]

[200] The last column in the table gives the deviations of the points obtained at the end of a series of observations as compared with the values, corresponding to the same scale divisions of the bi-filar scales;



Eichung ✱ vor und ◎ nach der Messung.

Fig. 12.

found by interpolation based on the calibrated curve plotted at the beginning of the series. Figure No. 13 represents the region of maximum deviation on a scale enlarged five times. In the other series of experiments here presented the calibrations taken before and after the observations displayed an equally good agreement. [201] When the smallness of these deviations is considered, it must be assumed that the errors in the determination of the discharge potential reduce essentially to the errors in Müller's measurements of potential. But according to the above table, and also the remaining data of Müller, it cannot be assumed that these errors exceed ¼%. But the interpretation of the data in favor of the sphere-theory would require an error of about one per cent.

As Einstein kindly pointed out to me, it is important to estimate the error which arises due to the fact that [202] rays undergo a certain deflection during acceleration, owing to the leakage of the magnetic field in the part of the discharge tube between A and K. The conclusions from the measurements are not affected by the absolute value of this deflection, but only by its variation during a run.

The magnetic field produced by the coils had as the first diaphragm A (i. e., where the accelerating field ended) a value about 3.2% as great as in the axis of the coils; from this point towards the cathode it diminished very rapidly, being too small to detect even with a current of .5 ampere at a distance of 5 mm. from the cathode; halfway between A and K the field was about 0.5 per cent as great as in the axis of the coils. These data were obtained with a ballistic galvanometer. Making the simplifying assumptions that the intensity of the field everywhere between A and K has this same "mean" value (0.5%), and that the electrons move with constant mass, we find that the trajectory would be a cycloid, the generating circle of which rolls on a straight line perpendicular to the beam. The equation for the curve is as follows: the x axis being the direction of the accelerating electric field and the y axis being perpendicular to the electric and magnetic fields.

$$x = \frac{P'}{\eta_0 s H'^2}\left(1 - \cos\frac{sH'c\beta_s}{P'}\right)$$

$$y = \frac{P'}{\eta_0 s H'^2}\left(\frac{sH'c\beta_s}{P'} - \sin\frac{sH'c\beta_s}{P'}\right)$$

P' is the potential in C.G.S. units producing the total acceleration, η_0 is the specific charge of the electron, s is the distance between the plates K and A, H' is the average magnetic field between K and A, and β_s is the ratio of the velocity at the point (x, y) to the velocity of light; all the quantities being measured in electromagnetic units. The angle between the x axis and the direction of the beam is given by

$$\frac{1}{2}\,\frac{sH'c\beta_s}{P'}$$

[203]

At the point $x = s$, the final velocity found from the discharge potential is $c\beta$. If the initial and final values of β for a run are substituted in the above formula, we obtain for both cases the inclination of the rays to the x axis at diaphragm A. We then can estimate the error due to leaving out of consideration the deflection of the rays during acceleration. It was computed for the runs given in Table I and Table VII. In the former case the change in angle is 4 seconds, the mean inclination being 3.3 minutes; in the latter, the change is 7 seconds on a mean inclination of about 5 minutes. Supposing the entire beam rotated through this angle about [one of the] crossed threads as axis, we get for the displacement of the phosphorescent spot .0033 mm. in the first case and .0056 mm. in the second. The displacement of the spot thus varies between 0.17 and 0.28 Promille of the total deflection. Considering the smallness of this error due to the deflection of the rays in the accelerated part of the discharge path, an effect upon the conclusions from the measurements is hardly to be expected.

C. Summary and Conclusion.

The experiments herein described have shown that the maintenance of high voltages up to 90,000 volts is possible in a high vacuum without the occurrence of spontaneous discharge, and that very rapid cathode rays are obtained in this way ($q > 0.5\,c$). The velocities obtained in this way are decidedly less than those of the most rapid β-rays, but the electron rays accelerated by electric fields have the advantage over the β-rays of homogeneity, and therefore, are sepecially suited to accurate measurements.

The most important result of these experiments, [204] however, is their contribution to a decision between the antagonistic theories of Abraham and Lorentz-Einstein. The measurements which we have given support the latter theory. As is well known, Bucherer arrived at the same results. However, the hitherto available results of observation are not sufficient to afford a criterion of this question of the validity of the principle of relativity which is so important to the entire subject of physics; and perhaps not to physics alone. For this reason, it is much to be desired that further experiments be performed with the greatest possible variation of method, and involving the more widely different type of physical phenomena.

This investigation was made in the Physics Institute at the University of Berlin under the direction of Professor Doctor Rubens.

[TRANSLATION]

CONCERNING SLOW CATHODE RAYS[1]

By O. v. Baeyer

[168]

For the specific charge of the electron, the measurements with slow cathode rays as distinguished from determinations with rays of greater velocity have given results of very poor agreement. In particular this holds for the method given by J. J. Thomson[2] for the determination of the path of the electrons which move in a homogeneous electric field and a magnetic field at right angles to the electric field. In the following I have investigated the peculiarities of slow cathode rays to explain a ground for these departures, and indeed the following points were especially considered in a more exact investigation:

1. The production of the most homogeneous slow cathode rays of great intensity by means of glowing oxide cathodes.
2. The ionizing power.
3. The determination of their velocities (in volts),
4. Secondary radiation or reflection.

Lenard[3] has investigated slow cathode rays produced by the photo-electric effect. The electrons leaving the cathode through the agency of ultra-violet light have, according to his investigations, considerable initial velocities, and indeed about 70 per cent of the aggregate have initial velocities above zero.

One cannot therefore in this way obtain a true homogeneous radiation with small velocity.

I.

On the other hand for this purpose the method of Wehnelt[4] for the production of electrons from glowing oxide cathodes is clearly superior. In general the electrons escaping from the glowing oxide possess initial velocities, as already shown by Elster and Geitel.[5] The consideration of the saturation curves on such electrodes shows, however, that the number of electrons escaping with noticeable initial velocity is vanishingly small in comparison with the total.

In analogy with the views of Lenard one obtains the number of the particles escaping with initial velocity by measuring the current which flows from the uncharged glowing oxide to its surroundings. All saturation curves of this kind show a very steep drop at zero. A more exact investigation of this point is, however, impossible without further means. If one uses, for example, an electrically incandescent wire inside a coaxial cylinder and measures the current flowing from the wire to the cylinder by a galvanometer, then since one connects either the positive or negative conductor of the heating current with the galvanometer and thereby with the cylinder, one obtains a positive or negative potential which corresponds to the potential difference on the wire.[6] Further, the magnetic field set up on the surface of the glowing wire by the considerable heating current eventually influences the whole slow cathode rays. To eliminate this difficulty, I have used for all measurements[7] a motor-driven mercury commutator which in its revolutions (five to ten times per second) closes the circuit first to the heating current, and while this is opened the circuit to the galvanometer. In this way only the electron current is measured which exists when the wire is still glowing, but not traversed by the heating current. The arrangement for the taking of the saturation curve is shown in the following Figure 1.

C is a cylinder brought into the evacuated tube, D the heating wire coated with calcium oxide. The conduction of the heating current goes from battery B over the two contacts of the commutator. The other side of the commutator connects one of the conductors of the heating current with the galvanometer, whence the current flows from the source of potential to C, the source of potential being a variable shunt resistance W, whose terminals are connected to battery B_1. The correct [169] operation of the commutator can then be adjusted so that the commutation of the heating current has no influence on the deflection of the galvanometer. For the taking of measurements there was used a Siemens and Halske galvanometer (sensitivity 5.10^{-10} amperes per scale devision) which could be shunted with a known resistance for the measurement of large currents. The shape of the saturation curve is shown by curve 1, Figure 2. The current at $V = 0$ was especially tested. There was found throughout a value under ½ per cent of the value at 22 volts where the saturation current was closely approached. The arrangement afforded a means also of determining the number of electrons which escaped with a positive charge on D.

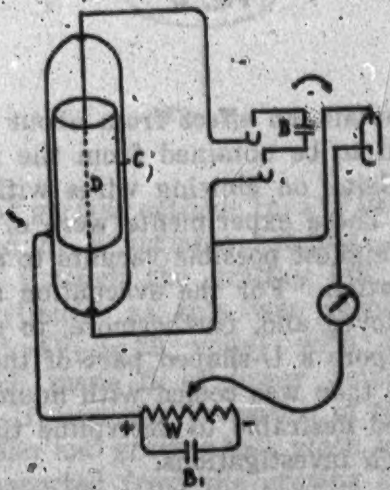

Fig. 1.

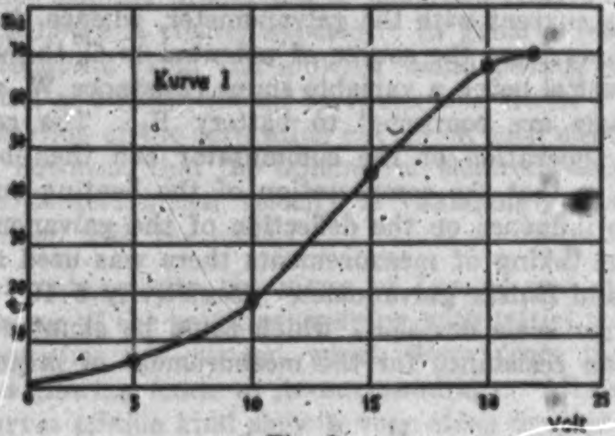

Fig. 2.

One can here obtain an effect from about 0 to 2 volts as was expected to be obtained from the investigation of Elster and Geitel on glowing wires without calcium oxide coating. These experiments were of course carried out in the highest possible vacuum to avoid the influence of ionization. For the evacuation a Kaufmann pump was employed and, furthermore, to remove mercury and fat vapors a U-shaped part of the connection to the discharge tube was cooled with liquid air. However, it appeared desirable to determine the ionization occurring in such investigations.

II. *Ionization of Slow Cathode Rays.*

Lenard[8] has shown that the limiting velocity of ionization for photo-electrically produced electrons lies at about ten volts. It does not appear certain without any further investigation that the same relations would hold with the very intense rays which we here use. The investigation was carried through in a manner analogous to that of Lenard. The glowing wire was surrounded by a cylindrical wire grating of 1 cm. diameter (wire diameter .1 mm., mesh .3 mm.); this was surrounded by a second cylinder of 2 cm. diameter. Between wire and grating cathode rays of various velocities were produced by a variable potential difference, V_1. These passed through the grating but did not reach the second cylinder, as this was placed at a negative potential ($V_2 = 20$ volts) with respect to the grating, which made it of lower potential than the heated wire. If, however, ionization of the gas contents between cylinder and grating took place, positive charges must be transported from the grating to the cylinder. If this ionization is considerable in comparison with the transported electrons, this current must be capable of detection by a galvanometer in circuit between the second cylinder and the grating. From $V_1 = 0$ to $V_1 = 10$ volts, no current was to be detected between the outer cylinder [170] and the grating. If, however, V_1 exceeded 10 volts a positive current from cylinder to grating appeared which rapidly increased with increasing V_1. This positive current did not become greater by an increase in

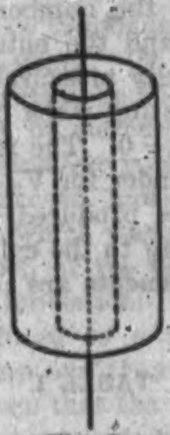

Fig. 3.

the negative potential of V_2 whence it follows that saturation was already reached. There was shown therefore a completely analogous relation to the case when the cathode rays of extremely small value were produced by the photo-electric effect. In order to determine the number of positive ions produced per electron, it is necessary to measure the number of electrons passing between the grating and the outer cylinder. For this purpose I simultaneously measured the current between outer cylinder and grating when both were at the same potential—that is, $V_2 = 0$. The ratio of the current between grating and cylinder for $V_2 = 20$ volts and $V_2 = 0$ gives the positive ions produced by an electron in its course from the grating to the cylinder and back to the grating. The measurements are collected in the following Table I.

TABLE I.

Voltage between cathode wire & wire net. V_1	Aggregate of the electrons passing from wire net to the outer cylinder (measured by the magnitude of the current at $V_2 = 0$)	Aggregate of the positive ions produced between wire netting and cylinder (measured by the current at $V_2 = 20$ volts)	No. of positive ions formed per electron
Volts	i —	i +	$\frac{i+}{i-}$
14	20,000 9)	16	0.0008
13	16,000	7	0.0004
12	13,000	4	0.0003
11	9,000	3	0.0003

The pressure in this investigation was about .01 mm. However, an exact determination of the pressure when glowing wires were used was excluded, for the same reasons I had to abandon the investigation of different gases, as determinations of the increase of the gas content due to the continuous evolution of gas from the wire and the continuously occurring occlusion of gases was impossible. Since the measurements showed that with the methods of measurement here used an ionization under 10 volts could not be detected, it is not necessary of course within these limits to take into account the errors of a still smaller ionization.

According to the views of Start[10)] this limiting velocity of ten volts, corresponds to the beginning of ionization in mercury vapor. To decide this point was of importance, as one should be able to use higher velocities by the elimination of mercury vapor in all investigations in which the smallest possible ionization is conditioned. I did not succeed, however, by the condensation of mercury vapor which was attained by the cooling of the U-formed branch of the tube with liquid air, in appreciably reducing ionization. For instance, the discharge tube was reduced to a pressure of .005 mm. with the mercury pump and then sealed off with a stop cock. It was found then that the velocity with a voltage of 14 volts on the wire grating was, for the current conditioned by positive ions, $V_2 = 20$.

$$i + = 50 \text{ scale deflections}$$

while the negative current carried by the electrons at $V_2 = 0$.

$$i - = 86000 \text{ scale deflections}$$

With the U tube cooled with liquid air, corresponding values were:

$$i + = 85 \text{ scale deflections}$$
$$i - = 106000 \text{ scale deflections.}$$

As one sees in both cases the number of positive ions formed per electron are very approximately equal. If the vacuum was raised as high as possible by the application of charcoal cooled with liquid air it was easily attained that the ionization with not too high velocities became no longer measurable by the methods here given.

III. *Velocity of the Rays Produced.*

With the same experimental arrangement an attempt was now made to investigate the velocity of the cathode rays produced. If one assumes that the electrons emitted from the incandescent wire pass through the wire grating with a velocity corresponding to the potential difference between hot-wire and wire grating, then no electrons can arrive at the outer cylinder when this has the same negative potential with respect to the grating as has the hot-wire. If the negative potential V_2 of the cylinder is now reduced by an arbitrary small amount then the total number (of electrons) passing through the grating should reach the cylinder. In the neighborhood, therefore, of this potential, the number of electrons reaching the cylinder should increase with extreme rapidity and maintain the same value with further lowering of the potential. It is here assumed that the electrons pass through the wire grating at right
[171] angles to its surface. The execution of the experiment gave the following results:

With very careful evacuation with the Kaufmann

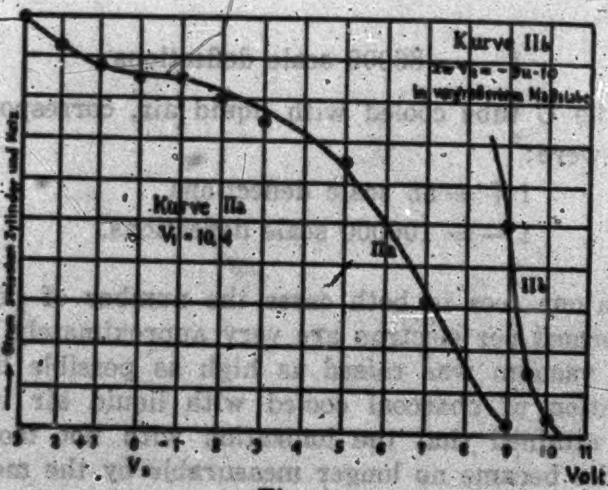

Fig. 4.

pump and cooling with liquid air of the connected U-tube, one obtained at $V_1 = 10.4$ a very sharp increase in the current i between cylinder and grating between $V_2 = 10.4$ and 9.0 volts. The curve II^b (Fig. 4) represents the characteristic of i from $V_2 = 9$ to $V_2 = 10.6$. It was noticeable that in the neighborhood of $V_2 = 10$ the current i was significantly affected by the kind of evacuation. For example, with evacuation by the mercury pump alone there was a deflection of six scale divisions for $V_1 = 10.4$, $V_2 = 10$, while the cooling of the U-tube with liquid air permitted the deflection to rise to 50 scale divisions, at which point the current sent out from the incandescent wire remained approximately constant. This showed that the electrons, which in this case had very small velocities in the neighborhood of the cylinder, were deflected, without the production of appreciable ionization, by the readily condensible part of the gas content, therefore in particular by the vapors of mercury and oil.

With a further decreased negative potential of the cylinder, however, the number of electrons caught by the cylinder constantly increased in the same measure; a constant value could not even be reached with a positive potential of about 4 volts. The characteristic is shown in curve IIa (Fig 4) in the region from $V_2 = -9$ to $V_2 = +3$. One may only conclude from this investigation that a small part of the aggregate rays pass through the wire grating with a normal velocity V_1.

The increase of the effect between $V_2 = 10$ and $V_2 = 0$ can be interpreted differently. One may assume that a considerable part of the electrons in passing through the grating experience a deflection by reason of the complicated character of the field in the neighborhood of the grating. A part of the electrons which with large retarding fields would be driven into the grating, will with small or accelerating fields pass through the meshes without striking the wires, reach the cylinder and thereby explain the increase of current.

Another possibility would be that the particles passing through the grating do not possess equal velocities. In this case, the particles must be given out not from the oxide cathode but from the gas residue, as is often assumed with visible cathode rays. In our case this is very improbable, as then ionization must have made itself noticeable.

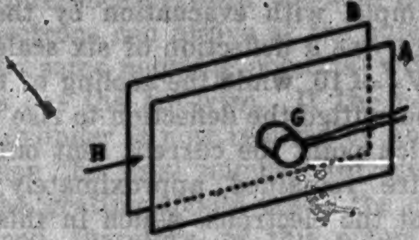

Fig. 5.

Finally one might assume loss of velocity on the part of the electrons by collision with gas particles. Lenard[11] in this way has explained observations of a similar character. In contradistinction to his research where the path of the rays was long (7.7 cm.) and the vacuum not very high (0.0025 mm.), in the investigation here described the path of the rays is only 1 cm. and the vacuum raised to the highest possible value with liquid air so that the departures in every case are not possible of explanation by this assumption alone.

To eliminate now as much as possible the influence of the wire grating, this was replaced by a diaphragm with which the inclination of the rays with respect to the surface of the diaphragm was as well defined as possible. For this purpose the incandescent electrode was placed in a hollow tube C (Fig. 5), the base of this tube was 2 mm. thick and was pierced with a few openings of 1 mm. size. This base lay on the middle of an [172] 8 cm. square brass plate A, and in the plane of

A. Finally there stood at 4 mm. distance an equal sized brass plate B, which corresponded to the external cylinder of the previous arrangement. As regards changes in the potential of the plate B, this investigation gave the same results as those of the foregoing part. With this arrangement, in case the rays were not influenced by the diaphragm, the rays passing through the diaphragm could proceed at most in a cone of about 54°. If one assumes that the rays of greatest inclination in every case had the velocity corresponding to the potential drop V_1, then the normal velocity component of these rays was v cos 27°. It would follow from this that these rays must reach the plate B in case V (the negative potential of B with respect to A) lay under $0.8 V_1$.

IV. *Secondary Rays: bzw. Reflection.*

With the last arrangement other disturbing phenomena appeared which admit of explanation, just as in the above described investigation, if one assumes a scattering of the rays by the metal particles encountered. Indeed, scattered rays were always present in the space between the plates A and B. Finally the effect, which has been already described by Thomson[12)] was of such a character that a weak magnetic field in the direction of the arrow (see Fig. 5) which could not noticeably affect the primary rays, yet caused a strengthening of the stream flowing from B. If one assumes a scattering of the rays by impact on B, the observed phenomena are simply explained by the bending back of the scattered rays which have a smaller velocity, at least normal to the impacted surface, than the rays striking the surface, and therefore are more easily influenced. In general hitherto a secondary radiation, reflection by metal particles, at the anode potential has not been known to exist for such slow rays.[13)] Lenard has found such secondary rays at velocities corresponding to 100 volts upward with a maximum effect occurring at 400 volts.

It was therefore necessary to devise an experimental arrangement which permitted of the certain detection of the presence of these secondary rays, bzw reflection. The experimental arrangement is shown in Fig. 6. In a cylindrical discharge tube, which was oriented in the direction of the earth's field, a brass tube A was placed. This tube was closed by a brass plate, in whose center a narrow brass tube B was placed (of 5 mm. diameter). The ring-shaped space between A and B contained a ring of brass foil which was insulated therein. At the top the ring-shaped space was closed by a wire grating C. This rendered it possible to impart to the ring an arbitrary potential difference with respect to its surroundings. D is a circular brass plate which may be lowered and raised. The cathode rays are emitted from the spirally wound platinum wire E, pass through B,[14] and fall upon D. The reflector D and the cylindrical member A are at the same potential with respect to the hot-wire. In order to permit the maximum possible rays passing through the grating C to reach R, the ring R is maintained at a positive potential with respect to C of the same value as that between A and E. If secondary rays or reflection is present, then an increase in

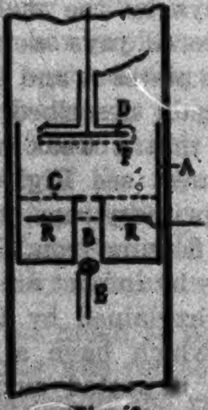

Fig. 6.

the number [of electrons] caught by the ring R must be capable of detection when the reflector is brought closer to the wire grating.15)

Once the current was measured between the ring R and A, in other cases between D and A. When by evacuation for many hours and the continuous application of liquid air the pressure was reduced to the lowest limit, and the rays had become fairly constant, the meas- [173] urements of the number [of electrons] falling on the reflector and on the ring for two separations of the reflector from the net C of about 17 and 7 mm. gave the following results:

TABLE II

Velocity of the primary rays in volts. (Potential difference between E and A)	Current in scale divisions between D & A		Current in scale divisions between R & A		Separation D — A in mm.
[illegible]	82	84	72	74	7
	85	89	62	67	17
4	66	65	98	93	7
	68	66	77	78	17
2 16)	14	—	38	—	5
	19	—	19	—	10

From this table one sees the following: The part of the rays reaching the reflector is approximately constant for the separation investigated. This shows that there is present no noticeable scattering of the rays by the gas residue. In any case at greater reflector separations the loss by scattering could be cancelled by the rays from the surrounding tube A. That this, however, could not be the case in any considerable degree follows from the fact that the quantity falling on D showed no marked diminution at very large separations up to 4 cm.

The current flowing from the ring R is in every case increased by the approach of the reflector D. This proves that the reflector is the source of rays.17)

If the separation between reflector D and grating C is further increased, the current flowing from the ring R does not further decrease in any considerable degree. As this is hardly to be explained by scattering of the rays by the gas residue, one must assume that the rays passing out of B which are considerably scattered by reflection on the inner walls of B, in their further course strike on the walls A, are there reflected, and so reach R.

Whether one has to do with secondary rays or diffuse reflection does not yet admit of decision. The same must be said of the question whether the observed phenomena proceed from the metal itself or from a gas film on its surface. Yet it may be established that the rays falling on the ring are of the same order of magnitude at the same velocity as the primary rays.

The increase of the current flowing from R is, in comparison with that flowing from D, larger with smaller primary velocities of the rays which signifies that the reflected number increases with decreasing primary velocity. If one compares this with the results of Lenard(18) who found a maximum of the secondary rays at a velocity of the primary rays corresponding to about 400 volts, then my research seems to say that one has here to do with another phenomenon. It appears that here a kind of diffuse reflection occurs, that is, change of direction of the moving particles by collision with molecules. In the latter investigation the cathode rays entered a space free from electric forces, so that the rays thrown back could move away from the reflector without any further agency. Furthermore, in the presence of an electric field which tends to retard the reflected rays, the reflected rays can cause disturbances under certain conditions.

If, for example, we place an incandescent oxide cathode at negative potential opposite a positively charged plate, in any case the rays reflected from the positive plate can not return to the cathode, since they possess at most a velocity corresponding to the potential difference between anode and cathode. If, however, the surroundings, for example the walls of the vessel, are raised to a positive potential with respect to the cathode, a part of the reflected rays can be intercepted and be incapable of detection. This is the reason why one can obtain true saturation curves only when one reduces the lateral deflection. So serviceable measurements with incandescent wires can be conducted only with an arrangement such that the incandescent wire is placed in the axis of a cylindrical tube whereby lateral deflections are negligibly small.

Lenard in his measurements has used a magnetic field in the direction of the rays to avoid lateral radiation. As one sees, thereby the influence of the herein described reflection is limited to the lateral diffusion. In any case, in the investigation of the photo-electric effect the matter is somewhat more complicated, as the [174] electrons so produced possess in considerable numbers noticeable initial velocities. Consequently a part of the number reflected from the anode may be returned to the cathode even with external accelerating fields.

Reflection must result in significant departures in all cases where the primary rays are retarded by an external field. In this way I believe that the departures from the results to be expected, as described in Part III, admit of satisfactory explanation.

V. *Avoidance of Reflection.*

The question now arises as to how this reflection is to be avoided. There are altogether three possibilities.

1. Application of an auxiliary field to restrain the reflected number (of electrons).
2. Application of the Faraday cage.
3. Selection of a suitable material.

I have adopted the method stated under 1 in that 2 mm. in front of the reflector D a fine wire grating F (0.15 mm. wire, 1.5 mm. mesh) was arranged which could be moved simultaneously with the reflector. While the grating was maintained at the potential of the surrounding [cylinder] A, the reflector could be brought to any desired potential. It was to be expected that with increasing positive potentials of the reflector D with respect to the wire grating F, the current flowing from reflector to A would increase up to the point where the auxiliary field sufficed to restrain the number of electrons reflected at D. In fact, the measurements showed a significant increase in the current up to a potential difference of 40 volts between the reflector and wire grating. That ionization in the space between reflector and wire grating did not here occur could be easily established by the fact that with a negative charge of 40 volts on the reflector with respect to the wire grating, no current flowing from the reflector could be detected.

From the measurements of the current flowing from D with and without the auxiliary field the ratio of the reflected to the arriving number [of electrons] could be approximately determined. Let i be the current flowing from the reflector without a field between grating and reflector, and i_1 the current in the presence of a field of such magnitude that a further increase (of the field) caused no further increase of the current. The practical part of the rays passing through the grating which is thrown back by the reflector in the absence of the field is then,

$$\frac{i_1 - i}{i_1} = r$$

The measurements gave:

TABLE III.

Velocity of the Primary Rays	i	i_1	r	
6 volts	9	52	0.83	Potential Difference between plate D and grating = 40 volts
	10	68	0.85	
8 volts	31	144	0.78	
	28	129	0.78	
16 volts	54	185	0.71	
	48	178	0.72	
	40	158	0.75	

From these measurements it follows that a considerable number of the rays arriving at D are reflected. The values found for the reflection factor r furnish a criterion for the magnitude of reflection. They can hardly be quantitatively correct as the sources of error were present in these measurements.

1. The reflection factor r gives in these cases the ratio of the number reflected at D to the number passing through the grating. One will therefore obtain the correct value when that part of the aggregate number which is absorbed by the grating is equal with and without the auxiliary field. This is not here the case as a part of the electrons, which without the field strike the wires of the grating, will in the presence of the field be bent away from the wires of the grating and reach the reflector through the meshes. Consequently the apparent value of r will be too large. The errors thus caused can, however not be large. For the part of the aggregate rays coming from the incandescent cathode which strikes the grating may be approximately calculated from the dimensions of the wire and mesh of the grating. It contributes in this case about ⅕ of the on-coming number [of electrons]. If one assumes the most unfavorable case, namely that this entire part reaches D in the presence of the auxiliary field, then $\frac{i}{i_1} = 1 - r$ comes out about ⅕ too small. For r itself there result these corrections in Table III.

For 6 volt rays r = 0.80 instead of 0.83
For 16 " " r = 0.68 " " 0.73

2. The second source of error to be considered is the disturbing field which exists such that the lines of force of the field between reflector and grating reach out into the space outside the grating.

This field will so act that those rays, which in the absence of this field reach the walls of the tube by rea-

[175] son of scattering by metallic particles or by the gas residue, or also by the formation of carriers, strike on the grating and the reflector. To avoid this source of error as completely as possible two diaphragms were placed in the tube of 2 mm. opening and 5 mm. separation. The result was that the scattered rays which arrived at the ring R were reduced to the tenth part of the number caught by the reflector, whereas in the previous investigation both numbers were of about the same order of magnitude. It was still necessary to determine by investigation the magnitude of these errors. For this purpose the reflection factor was determined for different separations of the reflector while the grating was moved simultaneously with the reflector.

The measurements gave for 10 volt rays:

TABLE IV.

Separation between grating and diaphragm	$\frac{i_1 - i}{i_1}$	i
3 mm.	0.74	88 scale divisions
8 mm.	0.70	97 " "
16 mm.	0.79	72 " "

From these numbers it follows that the quantity $\frac{i_1 - i}{i}$ is on the whole constant within the separations investigated. Still one recognizes that with very small separations, the disturbing field brings out rays from the space within the diaphragms whereby the reflection factor is apparently increased. With increasing separation this effect decreases. At the same time a still further increased separation results again in an increase in r, which is explained by the fact that with the application of a field between grating and reflector, rays, which in the absence of the field do not reach the grating, are drawn thither by the lines of force external to the grating, which in effect of course again conditions an apparent increase in r. The numbers given in Table III are based on a separation of about 8 mm.

Velocities of the rays under 6 volts could not be used in these investigations, since then the intensity was too small to measure on account of the diaphragm in B (Fig. 6). In the investigated interval between 6 and 16 volts, different values were obtained which show one significant phenomenon; for small velocities larger reflection factors. In accordance with the foregoing considerations one could trace this back to the stronger scattered rays with smaller velocities. From the previous investigations, which in this particular aspect are free from ambiguity, it likewise results that the reflected number increases with decreasing velocity, so that such an increase is established beyond question. As mentioned above, this is in agreement with the view that one has here not to do with secondary rays, as in Lenard's investigation, but with a simple scattering as has been also shown for gases.

VI. *Repetition of the Experiment under III with Avoidance of Reflection.*

In the measurements given under III of the velocity of the cathode rays, it was already mentioned that the presence of reflection would considerably influence the measurements. It was interesting, therefore, to investigate for such a case the effect conditioned by the suppression of reflection. Such an investigation was undertaken with the arrangement last described, in which a variable retarding potential was impressed between the grating and the outlet diaphragm. Whereas in the previous investigation with increasing retarding fields from a zero field up a systematic decrease of the current flowing from the intercepting plate resulted, now an entirely different characteristic curve appeared. In curve 8 (Fig. 7) the original velocity of the rays is 10

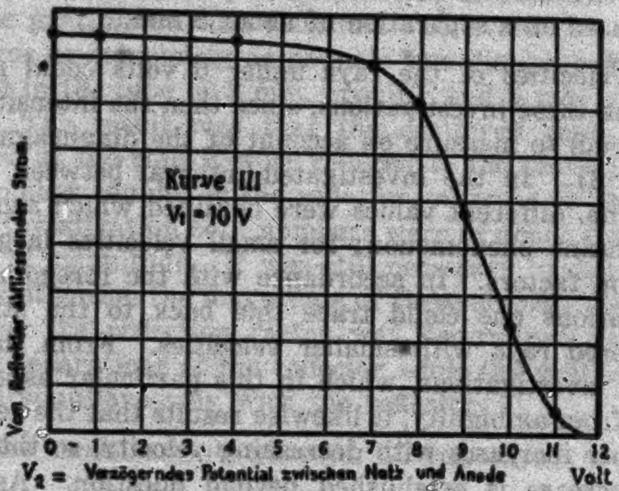

Fig. 7.

volts. As one sees, the number of rays striking the reflector remains constant, when the negative potential V_2 of the grating with respect to the diaphragm increases from 0 to 8 volts. Here begins a more rapid decrease of intensity up to $V_2 = 11$ volts. This interval, which is still considerable, in which the velocities of the rays appear to lie, cannot be traced back to an actual non-homogeneity of such magnitudes. Rather in explanation of this phenomenon the circumstance suffices that in this experimental arrangement neither the plate [176] D nor the grating is of infinite extent. For this reason rays which are emitted in a direction not exactly normal to the diaphragm but which with weak retarding fields between the grating and the diaphragm still arrive in the region of the grating with stronger retarding fields are forced off and laterally deflected.

The research herewith described has established the presence of a phenomenon similar to reflection with slow cathode rays. There is still required searching investigation to determine how this reflection depends on the material, the angle of incidence and above all the velocity of the primary rays. The determination of the velocity and specific charge of slow cathode rays will be improved on the basis of the views here given.

9. These large deflections are not directly observed, but calculated from the deflections with properly chosen shunt resistance.

10. Stark—Phys. Zeitschrift 5, 51, 1904.

11. Lenard, Ann. d. Phys. (4), 12, 726, 1902.

12. J. J. Thomson, l. c.

13. The known phenomenon that cathode rays as such are reflected from a plate has here no bearing. This appears when the plate has the potential of the cathode and is to be explained by electrostatic deflection.

14. The diaphragm shown inside B in the figure had to be omitted in order to attain the necessary intensity.

15. The arrangement is similar to that used by Stark (Ann. d. Phys. (4), 3, 75, 1900). While, however, with the arrangement of Stark only that part of the rays conditioned by scattering was influenced by displacement of the reflector, while the reflected number remained constant, on the other hand with the above arrangement a change in the quantity of electricity flowing from the ring R with change of position of D is only to be explained by the presence of secondary rays or reflection.

16. The measurements at two volts velocity had to be conducted at small separation on account of the feeble intensity.

17. By a special investigation it was established that the auxiliary field between the ring R and the net C conditioned no sources of error by its action outside the net. For this purpose the net C was completely removed and the ring given the same potential as the surrounding. The measurements gave qualitatively the same results.

DEFENDANT'S EXHIBIT No. 23.

UNITED STATES PATENT OFFICE.

CHARLES J. THATCHER, OF UPPER NYACK, NEW YORK.

METHOD OF EXHAUSTING VESSELS.

1,028,636. Specification of Letters Patent. Patented June 4, 1912.

No Drawing. Application filed March [illegible], 1910. Serial No. [illegible].

To all whom it may concern:

Be it known that I, CHARLES J. THATCHER, a citizen of the United States, and a resident of Upper Nyack, in the county of Rockland and State of New York, have invented a certain new and useful Method of Exhausting Vessels, of which the following is a specification.

The process which constitutes this invention relates to the exhaustion of any vessels whatsoever in which it is desirable to rapidly and economically attain high vacua. It may be used either for exhausting electrical apparatus which are permanently provided with electrical conductors or terminals, such as incandescent lamps, vacuum tubes, etc., or for exhausting non-electrical apparatus provided with suitable conductors or terminals only for the purpose of exhaustion.

The object of this invention is therefore to attain high vacua in any vessel requiring complete exhaustion, and the invention consists in effecting this in a rapid and economical manner without introducing into the vessel, or otherwise employing, any gas absorbing substance.

It is well known that complete exhaustion of vessels to high vacua by mechanical pumping alone is a slow and somewhat costly procedure. The difficulty lies in the exhaustion of the last traces of gas.

My invention relates more particularly to the rapid removal of these last traces of residual gases remaining after mechanical exhaustion.

At the present time, so far as I am aware, the only process of rapid exhaustion is that used in the manufacture of incandescent lamps and set forth in U. S. Patent #537,693 to Arturo Malignani. Three steps are essential to the operation of this process. They are the preliminary mechanical exhaustion of the lamp to a pressure of about 2 mm. of mercury; the intensive incandescence of the filament of the lamp in this attenuated atmosphere and at a sufficient intensity to produce a characteristic faint bluish haze throughout the interior of the bulb; and lastly, the vaporization of a suitable solid substance, such as arsenic, iodin, sulfur, phosphorus, etc., previously deposited in some convenient locality within the interior of the lamp bulb. The process of said patent also comprises additional elements or steps which I consider tributary to the three fundamentally essential elements above referred to. These tributary steps have been modified in Letters Patent, and in commercial practice to some degree, as regards the means employed for carrying them out and the sequence of their performance. Otherwise the modern practice of incandescent lamp exhaustion is substantially identical with that devised by Arturo Malignani in 1894 and disclosed in his Letters Patent. In all of these modified procedures as well as in the Malignani process itself, the extraneous solid substance deposited within the lamp combines with and precipitates, when it is vaporized, practically all of the gases in the lamp interior, accompanied by the disappearance of the blue haze.

My process, as applied to incandescent lamps, differs from that just considered in that I secure a high vacuum without the use of any such extraneous solid substance. I extend the preliminary mechanical pumping so that a vacuum is obtained which is generally higher than that proscribed by Malignani or than that attained by mechanical pumping in the practice of his process. I then institute the intensive incandescence, proper, of the filament, whereupon a decrease of pressure which is equal in extent and rapidity to that produced by the Malignani process at once occurs.

The exhaustion of lamps from 2 mm. down to say 0.2 mm. is therefore effected by my process merely by the continuation of mechanical pumping instead of by the use of vapors of solid substances as by Malignani. The completion of exhaustion, i. e. from 0.2 mm. down is effected by the same means in both processes, namely by the intensive incandescence of the filament for the same length of time and with the same result, as has been shown by investigation. Operating in this manner, the use of suitable substances as disclosed by Malignani may be entirely dispensed with and an equally high vacuum is obtained in substantially the same time—or even less as I will later show. Since this method of procedure does not vary in any manner the degree or duration of the intensive incandescence of the filament as now employed in the exhaustion of incandescent lamps, it is obvious that the filaments will not undergo any changes which do not occur in the [illegible] exhaustion now universally employed, and that they are therefor not injured by the practice of my process.

It has been demonstrated that filaments which are ordinarily used in incandescent lamps have initially a certain ability to precipitate gases in comparatively high vacuum, but lose this ability after they have been incandesced for a period, particularly at voltages above those they are designed for. The ability of these filaments to precipitate the gases in comparatively high vacua is limited, moreover, as to the amount of gas which they are able to remove. There exists, in other words, a certain proportionality between the size of a filament and the amount of gas which it will precipitate; at all events, this is borne out by the fact that a rapid reduction of pressure to very high vacua occurs with certain small and limited quantities of gas at certain low pressures, but does not with larger quantities at higher pressures. In view of these considerations it is apparent that the practice of this process in vessels containing solid conductors requires the use of a conductor or filament which has not previously been lighted for any appreciable time, particularly at intensive incandescence, and requires also a suitably extended preliminary mechanical exhaustion of the vessels. It was the realization of the necessity of these conditions and the practical application thereof to the exhaustion of vessels without the use of extraneous suitable substances which enable me to devise the herein described process. This limited precipitating power of electrical conductors may be termed their normal, intrinsic precipitating power, for it represents that normal quantity of gas which can be rapidly removed from a rarefied atmosphere without any pronounced or recognizable disruptive effects on the conductor itself, and which removal is occasioned by phenomena which are intrinsic to an electrical conductor during the passage of a current. This normal, intrinsic precipitating power can be readily ascertained by a few appropriate trials with any suitably arranged apparatus. By decreasing, step by step, the pressure in the apparatus before the current is first passed through the conductor in each trial, a certain pressure will finally be reached in which a decrease of pressure down to a very high vacuum occurs with great rapidity. The normal, intrinsic precipitating power will always vary, naturally, with the size and nature of the conductor, the intensity of the current passed therethrough, and, apparently, with the nature, condition and size of the walls of the vessel. In view of these many factors, it is impossible to specify the maximum quantity or pressure of gas which can be exhausted from any certain piece of apparatus, but by means of the directions above set out, any one skilled in procedures of this nature will readily ascertain the normal, intrinsic precipitating power of a conductor during the passage of a current of a suitable high intensity.

In lamps containing carbon filaments it has been customary to attach the filament to the leading-in wires by means of what are technically known as clamps. These latter are composed usually of a paste composition containing carbonaceous materials which decompose when the filaments or clamps become red hot, and evolve gas in considerable quantities thereby. For this reason the carbon filaments of the lamp have to be "worked" as it is termed, either during the final stages of mechanical exhaustion or immediately thereafter. A very high vacuum cannot be attained or maintained in any incandescent lamp containing such or similar clamps until these gases have been evolved.

In carrying out the herein described process which constitutes my invention, with vessels containing solid conductors and clamps of this character, it is obviously necessary, in order not to destroy the normal, intrinsic precipitating power of the filament, to effect the working of the clamps without any considerably extended incandescence of the filament. I may employ any means to effect this result, but have found in practice that the carbon filament of an incandescent lamp is still able to precipitate gases at a pressure of 0.3 mm., more or less, provided the working of the clamp has been carefully and rapidly executed. That is, the filament is not injured for the practice of my process providing the clamps are worked by first turning on the current after the pressure has been reduced to about one millimeter, or preferably less, by mechanical pumping, and while the same is continuing then increasing the current rapidly to the minimum intensity which will cause the clamps to become red hot in a few seconds. I maintain the filament and clamps at this degree of incandescence for a few seconds longer and then immediately shut off the current and continue the pumping down to the necessary low pressure corresponding to the normal, intrinsic precipitating power of the conductor. In carrying out this working, I must emphasize, it is advantageous to initiate it at a tolerably low pressure, something less than one millimeter, for the clamps then more readily acquire and retain a red heat.

After practically all the gases contained in the filament and clamps have been thus evolved, and the lamp has again been brought down to a suitable low vacuum by continued pumping, I institute the intensive incandescence of the filament proper, that is I bring the current voltage up to a sufficient intensity to produce the blue haze phenomenon, and maintain the same until the blue haze disappears and the desired almost perfect vacuum is attained; 30 seconds more or less are usually sufficient. Any other means of evolving the gases from the filaments and clamps or any means which would obviate the necessity of such a procedure may be employed in combination with my method of removing gases at low pressures. In lamps containing filaments and clamps of any description which would not evolve gases in any detrimental amount upon the initial incandescence of the filament this working in the above described manner, or in any other, may be, of course, dispensed with. In a somewhat analogous manner, traces of residual gases may be removed from vessels by passing a suitable current through the gases themselves by means of terminals. The current must be sufficiently intense to overcome the resistance of the vacuous space, and to suitably ionize it and produce a pronounced luminous discharge in the vessel practically until the desired final gaseous pressure is obtained. In this modification, also, the amount or mass of residual gas within the lamp should not exceed the normal, intrinsic precipitating power of the electrically excited conductor, which value may be ascertained for any type of vessel by a few appropriate trials as before explained.

A treatment similar to the "working" before referred to may be carried out in vessels containing gaseous conductors, provided it is rendered necessary by the presence of substances, on or near the terminals or in other interior portions of the vessel, which might evolve gases either during the process of exhaustion or in actual use. Any vessel, indeed, exhausted by my process, should be previously heated by some suitable means sufficiently to drive off from the interior walls the films of water or gas which normally adhere to the surfaces of solids. After either or both of these treatments have been effected and the gas or vapor thus evolved has been pumped out until a suitable pressure corresponding to the normal, intrinsic precipitating power of the conductor has been reached, the process of exhaustion is completed by passing a current of suitable intensity through the vessel as before explained, and preferably after the pump has been shut off.

My process can of course be carried out by other means and in other ways than those specifically described. For example, the exhaustion of incandescent lamps can be effected by the passage of a suitable current, not through the filament of the lamp itself but through a supplementary solid conductor or even through the residual gases of the lamp, after the filament has been worked as before explained if necessary, and after the lamp has been exhausted by pumping or other means to a pressure corresponding to the normal, intrinsic precipitating power of the conductor used for this purpose. This procedure would be preferable in lamps containing very sensitive filaments, which would be damaged by even a brief period of intensive incandescence, and in low voltage lamps. My process may, indeed, be thus carried out with lamps of any description whatsoever, in which it is thought that the filament is unsuitable, or might be injured by reliance upon it, to effect exhaustion as herein set forth. Such a procedure entirely dispenses with even the period of intensive incandescence of the filament now employed in the exhaustion of incandescent lamps and obviates any damaging effects to the filament arising therefrom. One method of safeguarding the filament in this way would be to effect the exhaustion by the passage of a current through the gases of the lamp by means of suitably applied external terminals or auxiliary internal terminals.

It will of course be understood that I do not confine myself to the specifically described methods of passing electrical currents through exhausted vessels or suitably ionizing or electrically exciting the gases in their interior.

By exhausting vessels according to the herein described process certain practical and important advantages result. Thus it is economical to dispense with the use of a suitable gas-absorbing substance in exhausting incandescent lamps. Although the process of exhaustion now employed requires the use of a very small amount of a suitable substance such as phosphorus, the total cost of the same and of its deposition in the tubultures of large numbers of lamps is considerable. By my process the tubulture can be made shorter. The consequent saving in glass tubing amounts to a further considerable item.

Incandescent lamp exhaustion by my process is also more economical than the present practice in that it requires less attention on the part of the lamp operator and is, in reality, more rapid. A comparatively large number of lamps can be attached to each pump and the mechanical exhaustion can then proceed while the operator is attaching or attending to another series of lamps. After the proper vacuum has been reached, as ascertained if desirable by a reading of the gaseous pressure by means of a suitable gage attached to each series of lamps, the current can then be turned on in all of the lamps simultaneously and continued until the exhaustion is completed. A determination of the pressure common to all the lamps can now be made again and in a very few seconds by the said gage, to insure that the requisite high vacuum has been attained; or the disappearance of the blue haze may be relied upon to determine this point. By a suitable arrangement of gas jets the lamps may then be all sealed off simultaneously and the current finally turned off. With a fairly good pump, a vacuum of 0.2 mm. or less can be attained in considerably less than 2 minutes as contrasted with the 20 to 60 seconds of mechanical exhaustion now employed in the operation of the Malignani process. But then allowing as much as 5 minutes for mechanical exhaustion, during which time the operator's attention can be given to another series of lamps, the exhaustion of a bank of twenty or more lamps by my process will not occupy ten minutes altogether, or less than 1 minute per lamp. This method of procedure, rapidity of exhaustion and output per operator cannot be duplicated by the present practice of lamp exhaustion, as each lamp requires individual attention and treatment on the part of the operator during the critical portion of the exhaustion. In addition to these advantages the herein described process is superior to that now in use in that it more perfectly insures the continuance of a high vacuum in the lamp during actual use. The gases are precipitated by my process in a more stable and permanent combination than by the present practice. The substance, phosphorus, which is now used, and which hold the gas in physical combination as I have demonstrated, is vaporized in the lamp bulb at comparatively low temperatures. The temperature which will produce this effect is easily reached during actual use of the lamp, and upon vaporization of the phosphorus it liberates some or all of the gas with which it is combined. The conditions under which the combination of the residual gases with phosphorus originally occurred are not duplicated in actual use. This liberation of gas and impairment of the vacuum, when once started, is cumulative and results in a considerable reduction in the useful life of the lamp. This effect cannot occur when my process is used, for the gases are precipitated and permanently held in combination with practically non-vaporizing particles such as carbon, tungsten or the like.

I claim:—

1. The process of rapidly producing high vacua in vessels, which consists in subjecting them to a suitable preliminary mechanical exhaustion, and passing a suitable electrical current through the vessels to complete the exhaustion.

2. The process of rapidly producing high vacua in incandescent lamps, which consists in subjecting them to a suitable preliminary mechanical exhaustion and passing a suitable electric current through the lamps to precipitate the residual gases and complete the exhaustion.

3. The process of rapidly producing high vacua in incandescent lamps, which consists in subjecting them to a suitable preliminary mechanical exhaustion, and then bringing the filaments to intensive incandescence to complete the exhaustion.

4. The process of rapidly producing high vacua in incandescent lamps, which consists in subjecting them to a suitable preliminary mechanical exhaustion and then bringing the filaments to intensive incandescence to precipitate the residual gases and complete the exhaustion.

5. The process of rapidly producing high vacua in vessels containing an electrical conductor, which consists in mechanically exhausting them until the mass of gas within the vessels does not exceed the normal, intrinsic, precipitating power of the conductor, and then passing a suitable electric current through the conductor to precipitate the residual gases and complete the exhaustion.

6. The process of rapidly producing high vacua in incandescent lamps, which consists in mechanically exhausting them until the mass of gas within the lamps does not exceed the normal intrinsic, precipitating power of the filaments, and then bringing the filaments to intensive incandescence to complete the exhaustion.

7. The process of rapidly producing high vacua in incandescent lamps, which consists in mechanically exhausting the same to a pressure not exceeding two-tenths of a millimeter of mercury, and then bringing the filaments to intensive incandescence to complete the exhaustion.

UNITED STATES PATENT OFFICE.

CHARLES A. FRIEDRICH, OF NEW YORK, N. Y.

METHOD OF PRODUCING HIGH VACUUMS IN X-RAY TUBES AND THE LIKE.

1,083,677. Specification of Letters Patent. Patented Jan. 6, 1914.

Application filed [illegible] 11, 1910, Serial No. 586,443. Renewed May 27, 1913. Serial No. 770,[illegible].

To all whom it may concern:

Be it known that I, Charles A. Friedrich, a citizen of the Empire of Germany, and a resident of New York, county and State of New York, have invented certain new and useful Improvements in Methods of Producing High Vacuums in X-Ray Tubes and the like, of which the following is a specification.

This invention has reference to a novel method of producing high vacuums in X-ray tubes and the like and pertains also to improved tubes of that type.

The known X-ray and like tubes and the methods heretofore employed for producing high vacuums required in such tubes are deficient. With the aid of the modern Roentgen apparatus it is possible to pass strong currents through the tubes but this involves certain disadvantages and greatly shortens the life of the tube. Furthermore with the former X-ray tubes, X-rays may be produced of but moderate penetrative power and more of the so called soft rays are produced than of the so called hard and penetrative rays because the inherent deficiencies of those tubes permit the passage of the current between the anode and cathode only after the vacuum has been regulated down to a certain height. If this regulation is not effected the current does not pass between the electrodes but discharges along the inner glass walls of the tube and causes irregular fluorescence of the entire glass bulb without producing X-rays. If under those circumstances a stronger current is applied then the tube is usually destroyed because it simply cracks. These deficiencies of the former X-ray tubes find their explanation in the method of their evacuation and in the disadvantageous location and construction of the regulating device.

In order to produce a lastingly high vacuum in an X-ray tube under present conditions when enormously strong currents are sent through the tube during use both the anode and the cathode should be heated to red heat during the evacuation so that all gases contained in the metal are driven out and removed by the air pump. The regulating device should not be on the outside of the tube but should be located within same near the center so that the gases absorbed by the regulator may be easily liberated for the purpose of forming a passage for the current.

The known methods of evacuation have the disadvantage that the same high potential current which produces the X-rays in the finished tube is also used for heating the electrodes during evacuation. The anode may thus be heated to red heat without causing disturbing secondary effects but not the cathode. The cathode acquires but little heat in a low vacuum and only after the cathodic rays become almost invisible it acquires heat quickly. If under those conditions the current is not shut off, large quantities of gas are expelled from the cathode while it acquires a red heat and the current finds an easy way through that gas layer and follows same. This causes that gases as well as volatilized metal vapors are thrown against the glass walls where they form a precipitate in form of a dark ring in the neighborhood of the cathode. A finished tube produced as described exhibits big disturbances around the cathode and such a tube is useless for practical purposes.

In the known methods of evacuation the cathode is not heated to red heat because it imperils the tube. As soon as the anode has acquired red heat the current is so reduced that the cathode will not be heated. For this reason current is passed interruptedly through the tube. A tube evacuated in the described manner still contains pretty large quantities of gas in the cathode and as the cathode easily acquires heat in a high vacuum these gases are set free during a continued use of the tube and the above described phenomena take place and the tube becomes useless in a very short time.

Another disadvantage of the use of high potential currents during the process of evacuation is that even at a low vacuum an electrostatic field exists in the tube which reduces to a large extent the efficiency of the air pump. As a consequence of this large quantities of gases which were expelled from the anode and cathode collect in the tube. By the continuous electric discharges and the static field produced thereby these gases as well as volatilized metal vapors are thrown against the glass walls and settle thereon. When the finished tube becomes cold this fine deposit on the glass walls absorbs part of the gases still contained in the tube and thus forms a fine gaseous layer on the entire inner glass wall. This explains why the current in a completely cooled finished tube passes easier along the glass wall instead of passing between the anode and cathode until the vacuum is regulated down.

In order to prove the existence of this fine gas layer on the inner glass wall reference may be made to a very simple method used years ago before regulating devices on X-ray tubes were known. When at that time a tube did not permit of the passage of the current between the anode and the cathode the tube was simply baked, that is, the tube was subjected to heat in a specially constructed oven. By this heat the gases absorbed by the deposit of metallic vapors on the glass walls were set free and accordingly the vacuum in the interior of the tube was reduced. Care had to be taken that the tube was not appreciably cooled off before current was sent through same otherwise the loose gases would partially be reabsorbed by the metallic deposit on the glass wall and no current for practical purposes would pass. As above mentioned gases and volatilized metal vapor settled on the cooler glass wall and when a high vacuum was produced the static field within the tube prevented quick excavation as required for practical purposes. The pump appears not to be able to draw the residual liberated gases through said static field in a higher vacuum and for this purpose an external regulator has been used. Such regulator consists of prepared asbestos, isinglass, or chemicals possessing a high degree of absorbing gases. After the process of exhaustion the residual gases are absorbed by the deposit on the glass wall and particularly by the prepared mass in the regulator. As a consequence of this the vacuum in the center of the tube is practically an absolute one, in other words the passage of the current between the electrodes is opposed in such a high vacuum by a tremendous electric resistance. For this reason it is easier for the current to find its way along the cooler glass wall where a thin gas layer still is found.

As above mentioned the regulating device on the tubes found in the market is in a disadvantageous location, on the outside and therefore too far away from the center of the vacuum. Such regulator is an encumbrance and necessitates a high auxiliary heating of the regulator mass. Such regulator on a former tube contains asbestos prepared separately before the regulator was fused to the tube and during handling the regulator it reabsorbs some vapors and moisture. Further when fusing the regulator to the X-ray tube water vapors are also formed from the blow pipe and the operator has to blow into the tube to join the regulator whereby more moisture is absorbed by the prepared asbestos therein. This absorption too has the bad effect of requiring a much longer evacuation. The regulator being outside of the tube causes that the vacuum will be too high between the electrodes for the passage of the current which passage is limited to a certain vacuum. This must be established by means of the regulator before the current will pass between the electrodes. It is however desired to obtain rays of greater penetration, that is, rays which are produced in a still higher vacuum than in the former tubes.

I have produced a novel X-ray tube and devised a novel method of producing a high vacuum therein by means of which high heating of both electrodes in a relatively low vacuum is effected without the use of high potential currents whereby all the deficiencies of the former method, secondary disturbing phenomena are eliminated and the glass walls remain clear and free from deposits. Furthermore there is no static field which prevents the continuous uniform action of the vacuum pump which with the new method can scope easily with the liberating gases from the electrodes in an unobstructed manner. To avoid deposits of metal on the glass wall no high potential currents are passed through the tube during the process of evacuation and the absorbent mass of the regulator is located near the center of the vacuum so that the passage of the current is not opposed by an almost absolute vacuum. The new X-ray tube thus made produces rays of higher penetrative power than those heretofore made.

The peculiar construction of my electrodes renders it possible to heat both the anode and the cathode simultaneously to red heat by means of the common current used for incandescent lamps. The absence of electrical discharges and the static field created thereby allows the pump to work with its full capacity whereby the liberating gases are quickly removed and cannot collect within the tube. Mercury vapors which formerly were produced within the evacuated space by the electrical discharges are accordingly not produced by my novel method and therefore not found in the finished tube.

To make the invention entirely clear reference is made to the accompanying drawing in which an X-ray tube is illustrated of my novel construction and exhausted according to my novel method and in which:

Figure 1 represents in elevation partly in section an X-ray tube embodying in desirable form the present improvements. Fig. 2 is a cross section on line 2—2 of Fig. 1, and Fig. 3 is a modification.

In the drawing *a* represents the glass bulb, *b* is a long glass tube for the anode integral with the bulb, *c* is a somewhat wider and shorter glass tube for the cathode also integral with the bulb and *d* is the remaining part or tip of the exhaust tube also sealed to the bulb by fusion. The anode passes through the long narrow tube *b* into the interior of the bulb and the cathode through the wider and shorter tube *c*. A terminal b^1 is formed at the top end of the tube *b* closing off same hermetically and a like terminal c^1 is formed at the bottom end of the tube *c* which closes off same hermetically. There are also two auxiliary terminals *e* and *f* whose purpose will be explained farther down.

The anode consists of a slotted steel tube *g* which has a longitudinal slot g^1 that extends through its greater length. At the end of the slot g^1 a lateral slot g^2 is formed. The slots are provided in the steel tube to impart some spring power so that the tube fits into and bears against the inner walls of the glass tube *b*. To the top end portion of the steel tube a metal wire, preferably a copper wire *h* is soldered to which the platinum wire *i* is fused which passes through the solid glass formed at the end of the tube and forms outside the anode terminal b^1. In the lower portion of the steel tube *g* there is the anode proper below the lateral slot g^2. The anode *j* is made of metal such as bronze or copper in the usual manner and secured to the steel tube by means of a screw j^1. Below the securing screw j^1 the steel tube is surrounded by an asbestos mantle *k* which is held in position by a metal ring *l* located on the bottom portion of the asbestos mantle and adapted to be tightened by a screw *m* passing through two side flanges of the ring as shown in detail in Fig. 2. Around the asbestos mantle the metal wire is wound preferably platinum wire *n* the one end of which is secured to the screw j^1 so that it is in electric contact with the steel tube *g* and the terminal for the anode. The second end of this wire around the asbestos mantle is secured to a short screw *o* which ends on the asbestos and therefore is not in electric contact with the anode *j*. As shown in Fig. 1 a conducting wire *p* leads from the tensioning screw *m* to the auxiliary terminal *e*. In this way a circuit may be established by means of the anode terminal b^1 and the auxiliary terminal *e* of which the high resistance metal or platinum wire forms a part and thus the wire *n* on the asbestos mantle may be heated by a low potential current without passing any current through the anode. As above stated street current or the common incandescent lamp current may be used for heating the high resistance wire *n* on the asbestos mantle and as may be seen from Fig. 1 both the asbestos mantle and the high resistance wire *n* are within the glass bulb near the center of the vacuum in the finished tube.

The cathode which is in the shorter and wider tube *c* opposite the anode consists of an aluminum rod *q* located in a narrow glass tube *r*. The bottom end of the aluminum rod connects with the terminal c^1 by means of a platinum wire *s*. The top end of the aluminum rod *q* is screwed into the cathode proper *t*. The cathode likewise is made of metal, cup shaped at the top and forms a thick rod t^1 below. The aluminum rod *q* is preferably screwed into the rod portion t^1 of the cathode while the glass tube *r* simply extends into an opening in the lower portion of the thick rod t^1. The glass tube *r* is fused to the solid glass portion through which the platinum wire *s* passes. Around the thick rod portion t^1 of the cathode *t* an asbestos mantle *u* is provided which is secured by means of a metal ring *v* adapted to be tensioned in the same manner as the ring *l* of the anode. High resistance or platinum wire *w* is wound around the asbestos mantle whose top end is secured to a screw *x* and thus in electric contact with the cathode. The bottom end of the platinum wire is secured by means of a short screw *y* to the copper ring *v* which screw ends on the asbestos mantle and therefore is not in electric contact with the cathode. In connection with the ring *v* is a small bar *z* which connects with the auxiliary terminal *f*. Thus a circuit may be established by means of the cathode terminal c^1 and the auxiliary terminal *f* of which the high resistance or platinum wire *w* forms part. In this manner the platinum wire *w* may be heated by common street current or the incandescent light current.

Assuming that the tube is in connection with the pump and is gradually exhausted then at a certain stage of the evacuation the platinum wire around the asbestos mantle is heated to incandescence. The asbestos mantle also gets hot and imparts heat to the anode below and after a certain time the anode proper acquires heat and becomes red. Simultaneously the cathode is heated in like manner. The gases contained in the metal of which the anode and cathode are made are gradually expelled and the liberating gases are at once removed by the air pump in an unobstructed manner because there is no static field within the tube. As both electrodes are heated in this manner no gases will be expelled from the finished tube when a high potential current is passed through same. No deposit is formed on the inner glass walls because there are no secondary disturbing phenomena within the tube under these conditions and there is no collection of gases as were retained in former tubes by the static field.

With the described construction of the electrodes in the tube and the novel method of evacuation a greatly improved tube is resulting whose glass walls remain clear from deposits. No gases can be expelled from the electrodes after the tube has been finished but over and above everything X-rays of higher penetrative power may be produced with such tubes.

When the finished tube made according to my novel method cools off the asbestos mantles naturally cool off too and as they are treated in the usual manner they absorb the residual gases within the bulb whereby an almost absolute vacuum is produced between the electrodes. If it is desired to use the tube current is passed through the platinum wire on the asbestos mantles whereby some gases are expelled right in the interior of the tube and almost in the path of the current. These expelled gases form so to say a conductive bridge for the high potential currents which then are passed through the electrodes proper.

In order to render the regulating device automatic the size of the platinum wire on the asbestos mantles is so selected that the strength of the current of the Roentgen apparatus is sufficient to heat that wire and thereby the asbestos mantles below same so that gases are expelled for the purpose of establishing a passage for the high potential current between the electrodes.

In Fig. 8 of the drawing a modification of the described device for heating the electrodes by low potential currents is illustrated. In this modified form the high-resistance or platinum wire on the asbestos mantle forms a closed circuit in itself and the heating of this wire and thereby the electrode is effected by induction from an outside primary spool of an induction coil C which fits over the glass tube *b*. The wire *n* then forms the fine wire of the induction coil and is heated when current is passed through the primary coil C. The platinum wire *w* on the asbestos mantle *s* of the cathode may likewise be heated by a suitable primary coil as described in connection with the platinum wire *n* on the asbestos mantle *k* of the anode.

I claim as my invention:

1. The method of producing a high vacuum in an X-ray tube which vacuum will remain constant during a single operation consisting in heating to red heat both the anode and the cathode during evacuation by means of low potential currents.

2. The method of producing a high vacuum in an X-ray tube which vacuum will remain constant during a plurality of operations consisting in heating to red heat both the anode and the cathode during evacuation by means of low potential currents.

3. The method of producing a high vacuum in an X-ray tube which vacuum will remain comparatively permanent consisting in heating to red heat both the anode and the cathode during evacuation in a relatively low vacuum by means of low potential currents.

4. The method of producing a high vacuum in an X-ray tube which vacuum will remain comparatively permanent consisting in heating to a cherry red heat both the anode and the cathode during evacuation in a relatively low vacuum by means of low potential currents, and expelling thereby all gases contained in both the anode and the cathode.

5. The method of producing a high vacuum in an X-ray tube which vacuum will remain comparatively permanent consisting in heating to high heat both the anode and the cathode during evacuation in a relatively low vacuum, expelling thereby all gases from the anode and cathode, and removing said gases as they are set free.

6. The method of producing a high vacuum in an X-ray tube which vacuum will remain comparatively permanent consisting in heating a regulating device on each electrode within the tube near the center of the vacuum in an independent circuit by low potential currents during evacuation in a relatively low vacuum, and expelling thereby the gases from both the anode and cathode.

7. The method of producing a high vacuum in an X-ray tube which vacuum will remain comparatively permanent consisting in heating a regulating device on each electrode within the tube in an independent circuit by low potential currents in a relatively low vacuum, expelling thereby the gases from both the anode and cathode and removing same as they are set free.

8. The method of producing a high vacuum in an X-ray tube which vacuum will remain comparatively permanent and expelling gases from regulators and both the anode and the cathode in one operation consisting in heating a regulator on the anode and one on the cathode within the tube in a relatively low vacuum by means of low potential currents in an independent circuit, expelling thereby gases from the regulator and the anode and the cathode, removing said gases as they are set free until a high vacuum is obtained, allowing the sealed off tube to cool and the residual gases to be absorbed by the cool regulator.

9. The method of expelling gases from the cathode of an X-ray tube and the like during evacuation consisting in heating a regulating device on the cathode by means of low potential currents in an independent circuit in a low vacuum whereby the gases contained in the cathode are gradually expelled.

10. The method of expelling gases simultaneously from both the anode and cathode

of an X-ray tube and the like consisting in heating a regulating device on each of them by low potential currents in separate circuits which are independent from the circuit of the electrodes, heating thereby gradually the anode and the cathode in a relatively low vacuum and expelling the gases contained therein and removing said gases.

11. The method of evacuating and automatically operating an X-ray tube and the like consisting in heating both the anode and the cathode in a low vacuum by means of low potential currents in independent circuits expelling thereby the gases from the anode, cathode and regulators removing same as they are set free until a high vacuum is obtained, allowing the sealed off tube to cool and the residual gases to be absorbed, and expelling the absorbed gases partially by the current of the Roentgen apparatus.

12. An X-ray tube comprising an anode and a cathode, and an electric heater on the anode and one on the cathode within the tube for the purpose of heating the anode and the cathode during manufacture.

13. An X-ray tube comprising an anode and a cathode, an electric heater on the anode in an independent circuit, and an electric heater on the cathode in an independent circuit, both within the globe.

14. An X-ray tube comprising a globe with central tubes thereon, an anode having an electric heater near its inner end within the globe, an auxiliary terminal for establishing an independent circuit, a cathode with electric heater near its inner end, and an auxiliary terminal for establishing an independent circuit.

15. An X-ray tube comprising a globe with central tubes thereon, an anode in one tube extending into the globe, a layer of asbestos near its inner end, high resistence wire thereon connecting with one end with the cathode and an auxiliary terminal connecting with the other end of said high resistance wire, a cathode, an asbestos layer near its inner end, high resistance wire on the asbestos connecting with one end with the cathode, an auxiliary terminal connecting with the other end of said high resistance wire so that independent circuits may be established for the purpose of heating the anode and cathode simultaneously but separately by low potential currents.

In the fall of 1906 my attention was attracted to a remarkable phenomenon, the investigation of which afforded the substance of the following paper.

This phenomenon—a red fluorescence obtained under certain conditions along the path of the electric discharge in vacua—was soon found to be something accidental and of minor importance compared with the new relationships to which the investigation of this phenomenon in high vacuum led. It was found that the potential gradient in the positive column of a luminous discharge does not, as was assumed on plausible grounds and found experimentally by Hertz,1) decrease without limit with decrease in gas pressure and approach zero, but that this holds only down to a certain maximum pressure, from which on the potential gradient increases again very rapidly with decreasing gas density.2) [674] The remarkable thing about it was that the mean free path of the charged particles carrying the current increases with decreasing pressure, and that consequently the obstruction to the current transportation should become less the better the vacuum.

If one works with a Wehnelt cathode,3) to simplify the matter technically and to avoid too high voltages, and finds that from a maximum pressure down the voltage across the terminals of the tube show a marked increase, one would be misled to conclude4) that in this region the oxide cathode does no longer show the property of reducing the cathode fall. An exploring electrode measurement shows, however, that there is no change in the behavior of the oxide cathode; that, on the contrary, a marked potential gradient accompanied by an intense heating of the glass walls in the positive column, appears when the gas pressure is reduced.

With this was given the substance for investigation: The highest possible vacuum was to be produced. In this vacuum a discharge was to be established with a current greater than a definite minimum value. The conditions were to be investigated in regions as far as possible away from the electrodes.

One can formulate more generally the conditions of high vacuum and large current density as follows: The production of a state *in which the volume density of the electrons carrying the current is as large as possible compared with the density of gas molecules, in which there exists, therefore, a tendency for the formation of the maximum possible space charge in the path* [675] *of the current.*[5)]

Under the conditions thus defined phenomena manifested themselves which formed the basis of my above mentioned publications and which pointed to the existence of positive carriers of small mass. I could not reproduce these phenomena since in a satisfactory way. In view of their importance they were primarily the spur to a thorough investigation of the discharge of electricity in extreme vacuum, in order to know and understand the conditions which were initially very variable. The results of this study form the substance of the present paper.

Even if a direct proof of the existence of positive electrons is not given by the following results, one nevertheless finds a number of relations which can be explained in a simple way on the assumption of the existence of positive carriers having a constant ratio of charge to mass, i. e., more specifically positive charges which exist independently of matter.[6)] The question regarding the existence of positive electrons may therefore, as far as my experiments go, be left unanswered, especially also because investigations of other experimenters and closely allied to my publications leave the question open. In fact I do not see a decision on the question either by the repetition of part of my experiments by Gehrcke and Reichenheim,[7)] Bestelmeyer and Marsh,[8)] which gave a negative result, or in the experiments of Jean Becquerel[9)] which gave an affirmative answer to the question of the participation of positive [676] electrons in gas discharge and in emission of light.

II. THE FLUORESCENCE COLORS OF THE GLASS IN THE POSITIVE COLUMN.

Before taking up the substance proper of the following investigation I want to give a summary of the most important observations made in my former investigation on the red fluorescence which was first made by me at the outset of these investigations.

The fluorescence appeared in the course of another experiment.10) I used a tube of the form shown in Fig. 1. The glass bulbs G_1, G_2 containing the cylindrical electrodes C — and C + were connected with the tube U (13 mm. wide). D consists of a glass rod and serves to support the structure; R is the connection to the pump. When this tube was filled several times with [677] oxygen prepared from potassium permanganate and evacuated while a discharge was passing it happened that when the pressure was below 0.01 mm. Hg. and the current about 20-30 milliamperes a red patch could be produced at any point of the tube U by the approach of a steel magnet. When the vacuum became

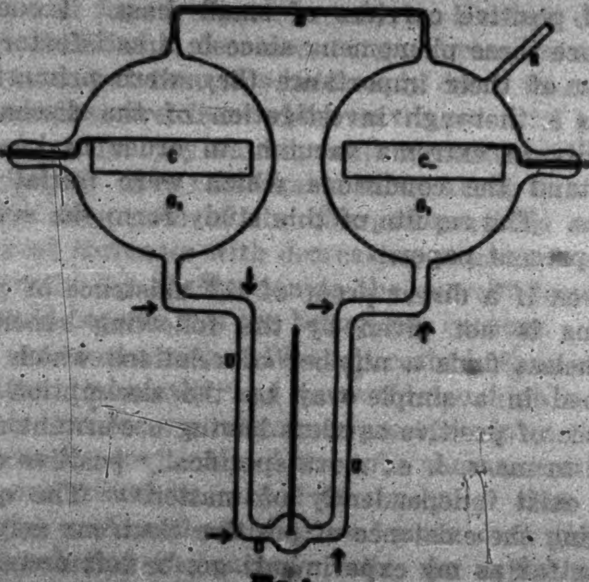

Fig. 1.

better cherry red patches appeared at the places marked with arrows, which could be distinguished from such as are produced by canal rays. The spectrum was found to be continuous in the red region.[11]

The position of the patches showed that they were produced by carriers passing from cathode to anode. In order to study the phenomenon in a higher vacuum I replaced the aluminum electrode C— by an oxide cathode. When, for example, this cathode was placed in the tube marked with — (Fig. 2) and the desired vacuum produced the red patch appeared at R. From a deflection experiment I concluded "that the negative corpuscles alone cannot account for the red fluorescence but that it was also conditioned by another factor."

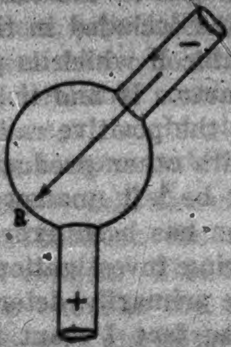

Fig. 2

I suspected that this second factor was due to positively charged carriers. At the same time I intimated that the minimum potential gradient mentioned in the introduction, which is established at a definite pressure "indicated that it is not only the electrons emitted from the oxide cathode which, as is often assumed, cause the discharge in high vacuum, but that the condition of electricity under the conditions mentioned depends very much on a second factor, which is perhaps made visible [678] to the eye by the red fluorescence."

In the next publication (No. 7) the red fluorescence and other fluorescence colors of the glass were mentioned for the last time as follows: "It appears on glass and quartz in a very high vacuum but not in most extreme degree of vacuum. If the vessels are freed from gases occluded in the walls by continued discharge the original cherry red fluorescence in the case of glass becomes red-violet to blue with a few sky blue places; in the case of quartz, however, the fluorescence becomes sky blue with a few green patches, and sometimes also other colors—which is due to the technical difficulties in the manufacture of quartz tubes.

"The red fluorescence consequently appears to depend on the residual gas in the tube, or what is more probable, with the gas occluded in the walls. The blue may be due to the silicon which is present both in the glass and in the quartz. If and in how far this fluorescence is caused by the positive radiation or rather by their joint action with other products of the discharge may for the present be left unanswered."

Since the opinion has been expressed by others, as well as in the following investigation, that the color of the fluorescence was primarily determined by the condition of the glass surface I want to say here briefly that from the beginning I have held the view that the fluorescence colors observed by me were due to a special kind of excitation of which I did not say anything definite except that it was not conditioned by cathode rays alone. In support of this view I pointed out in my first publication that the ordinary green fluorescence can be produced as well as the red by bringing a magnet close up to the bulb of Fig. 2. It is also possible by the use [679] of an auxiliary electrode to superimpose the ordinary yellow green fluorescence upon the pale blue,—especially in the case of the less marked bluish fluorescence which appears on glass walls that have been very well denuded of gases, and, after the red fluorescence had disappeared after a long continued discharge. Of the many possible ways of performing this experiment may be mentioned the one in which the platinum wire ring Z of Fig. 6 is connected with the cathode through a high resistance (electrolytic or the secondary of an induction coil): the upper opening of the narrow tube

E_2 immediately becomes filled with the ordinary Roentgen tube fluorescence.

In contrast to my experience and views are the following publications: Gehrcke and Reichenheim[12] ascribe the excitation of the fluorescence colors to the impact of cathode rays and regard simply the difference in velocity of the cathode rays as the deciding factor; slow cathode rays were supposed to give the red and presumably also the blue, and fast cathode rays the ordinary green fluorescence. This view was afterwards modified by Reichenheim[13] in that he supposed that the new fluorescence colors, especially the blue, were caused by the intensive emission of primary or secondary cathode rays. Reichenheim considered the possibility that also ions (canal rays) might play a part in the excitation—thus tending to some extent to favor my views.

Lastly, Goldstein[14] held the view that there might be some connection between the red fluorescence and gas mixture rich in oxygen. This fluorescence is indeed best produced when one fills the tube, during the discharge several times, as I did initially, with pure oxygen and evacuate. A red fluorescence is obtained especially when the tube has been previously filled with pure oxygen, and then also with much higher pressures than [680] when oxygen has not been used. And it seems that with oxygen the pressure can be increased without limit, provided that the current be large enough to give sufficient energy at the higher pressures to cause the red fluorescence.

It is, however, possible to also obtain the red fluorescence, without washing with oxygen, as follows: If the tube is evacuated for several hours during which the glass walls are strongly heated and during which time the absorption vessels give off hydrocarbon gases under strong heating in accordance with the method of evacuation described below, gases are introduced into the discharge vessel, which presumably do not contain oxygen in appreciable quantities and which indeed give a hydrocarbon spectrum. When now one of the absorption vessels be immersed in liquid air for some time and the discharge passed, one observed the red fluorescence with a persisting hydrocarbon spectrum, although this fluorescence is then not obtained in the same intensity as when the tube is washed with oxygen.

Also other facts to be mentioned in the course of this paper indicate that washing with oxygen and simultaneously discharging point out, as I have surmised in the first publications, the value of this method of purification of the walls of the vessel—a purification which could, however, also be obtained by an intense heating of the tubes in thermostats, although not so well as when both methods are combined.

In this connection it must be remarked that Konen[15] observed the red fluorescence in tubes which gave a pure helium spectrum.

Finally it may still be remarked that when one obtains the highest degree of evacuation which has only lately become possible the fluorescence of the glass walls assumes a peculiar grayish tint and that in general no appreciable change in the tint takes place when the tube is immersed in liquid air.
[681]

III. EXPERIMENTAL ARRANGEMENTS.

1. *The Production of the Vacuum.*

In the course of the work it was found that the principle on which the production of the vacuum is based if one tries to obtain extreme rarefication of the gas, can be put in a form as instructive as it is simple; the discharge tube itself must be kept, as far as possible, from the very commencement of the pumping at a considerably higher temperature than the connecting tubes, etc., especially if heated wood-charcoal, stop-cocks and joints tightened with fat, etc., are present in the connecting tubing. In fact it is apparent that these conditions prevent the distillation of all kinds of impurities from the sources mentioned. Consequently if the discharge tube is at room temperature, a part of the tubing which should be located if possible between the discharge tube and the joints, should be immersed in liquid air. If, however, the wood-charcoal tubes are deprived of gas by heating to a high temperature, then it is absolutely necessary to bring the discharge tube to at least as high a temperature; and on the other hand it is desirable to cool part of the tubing in liquid air.

The coconut charcoal which is used as an absorbtive material, must be heated to over 400° C. every time a vacuum is established and must be freed as far as possible from the gases given off by pumping for several hours with a rapidly working air pump (Gaede's Mercury air pump). I found it desirable, however, after operating the Gaede pump for several hours, to pump for some time with an air pump which draws less from the atmosphere (Neesen's mercury air pump as manufactured by R. Burger & Co., Berlin). Not till then is use made of the combined absorption process by filling with oxygen and evacuating.

The apparatus used is as follows: thermostats of [682] different sizes and of the form shown in figure (3) are used for heating the tubes, both the absorption

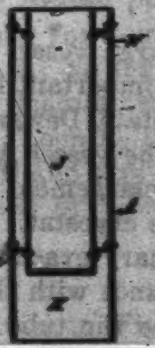

Fig. 3.

and the discharge tubes. An external iron tube A, covered with asbestos is open at both ends and has inside it an iron tube J supported by brackets W, which is open above and is closed by a plate below. There is an air space between the two metallic walls. In the space H there is a suitable heating flame (gas burner, etc.). It is considered to be a practical way of proceeding when working with such thermostats to construct the instruments to be heated so that their main expansion will be as much as possible in a vertical direction.

The vacuum tubing is shown in Fig. 4. The cocks H_3 and H_4, indicated diagrammatically, lead to the Gaede and Neesen pumps respectively. The absorption tubes A_1 and A_2 are constructed on the plan of a wash bottle, in order to precisely separate the parts of the tubing in front of the discharge vessel from those behind it, and yet have the discharge vessel in the form of a figure of rotation; this is important in connection with fitting vessels into thermostats, Dewar flasks and cryostats, for various reasons. The vessel A_2 differs from the vessel A_1, in having an enlargement E in the upper part for inserting it into the cryostat. The tube A_1 is used for [683] the preliminary evacuation of the entire system of tubing in accordance with the principle mentioned in the beginning, while the tube A_2 is joined to the discharge tube by a connecting tube about 25 to 30 mm. wide and as short as possible and serves to maintain the vacuum during the actual experiments. The exhaustion is carried out as follows: in the beginning the tubes A_1 and A_2 and the discharge tube are heated to over 400° C.

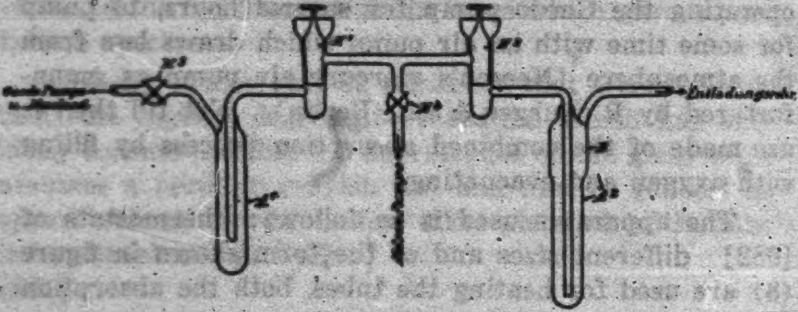

Fig. 4.

and the Gaede pump connected to the entire system of tubing. In the very first stage of the exhaustion the Wehnelt cathode is also raised to a red heat in order to deprive it of gas as far as possible at the outset. When the partial pressure over the heated wood charcoal is of the order of magnitude of 0.0001 (a Macleod manometer is connected with the Gaede pump) the Gaede pump is disconnected, the stop-cock H_3 closed, H_4 is opened and the Neesen pump set in operation. After a period of from one to two hours the tube A_1 is allowed to cool and is immersed in liquid air. The Neesen pump is disconnected, and the remaining traces of gas allowed to be absorbed in A_1 during a period of about three hours. Then the stop-cock H_1 is also closed and after the tube A_2 has been allowed to cool, the discharge tube is removed from the thermostat and is at once heated by an intense discharge current.[1] The whole system of tubing and vessels is filled several times with oxygen from the potassium permanganate vessel attached to the Neesen pump up to a pressure of several millimetres, then gradually evacuated with the Neesen pump and the last traces of gas removed each time by opening H_1 and absorbing in A_1. After the walls of the tube have been cleaned in this way, a condition which can readily be perceived after long experience, the Neesen pump is disconnected, the stop-cock H_1 is opened for some time and the remaining gas absorbed in A_1 as far as possible, a continuous discharge being maintained through the discharge tube all the while. Then A_2 is immersed in liquid air, the cock H_2 is closed and now the final degree of evacuation can be attained by a correspondingly long discharge.

[684]

The permanganate tube in Fig. 5 consists of the glass bulb G containing the permanganate; the capillary hook H serves to keep back the coarser dust during the heating of the permanganate, while the very fine dust is retained in the tube A, which is constructed like a wash bottle. The action of the tube is chiefly to retard the velocity of flow; its effectiveness may be increased by filling the space between the capillary tube K and the wall with glass wool and by putting in a capillary spiral S. Moreover the tube A may be cooled in liquid air if it is desired to retain the moisture which may be liberated by heating the permanganate. But this has no greater effect than the cooling of the part of the actual tubing between the ground joints and the tube A_2 in Fig. 2 by means of liquid air during the filling with oxygen. For this reason this complication is usually omitted.

---

[1] At this stage the red fluorescence mentioned on p. 680 can be observed in the absence of 0.

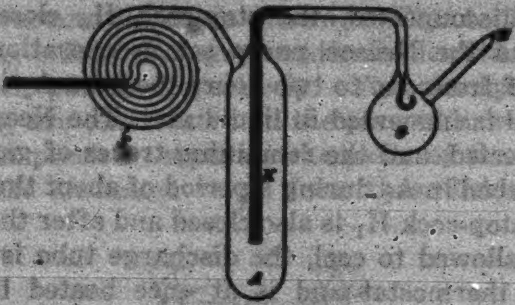

Fig. 5.

2. *The Discharge Tube.*

The construction of the discharge tube is based on the following considerations: *Firstly,* its expansion should be mainly in a vertical direction as mentioned in the description of the thermostats. This permits the tube not only to be heated but also to be cooled to the temperature of liquid air. *Secondly,* in order to save [685] the liquid air during the cooling, the heat generated at the Wehnelt cathode by the heating current should as far as possible be given off outside the liquid air bath. The light from the glowing cathode must be screened as far as possible in such a way that the spectral observations of the discharge can be carried on without hindrance. *Thirdly,* the oxide cathode should

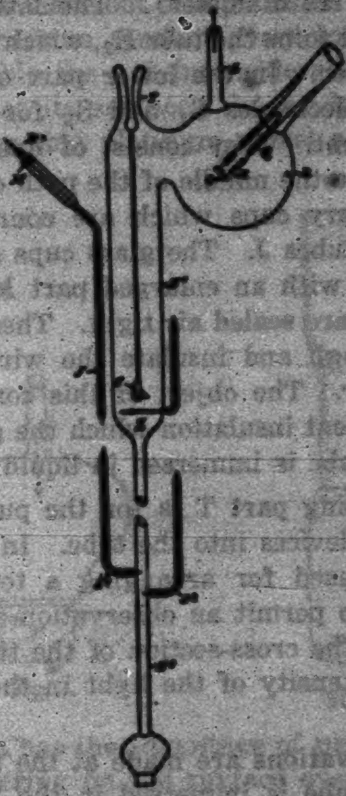

Fig. 6.

however, be connected as near as possible to the absorption tube, and, in contrast with this, should be separated from the part where the actual measurements are carried out by tubes as long and narrow as possible, in order that a dynamical equilibrium may be attained in which the gases given off by the cathode and absorbed by the wood charcoal diffuse as little as possible to the point where the observations are taken. These three considerations are the reason for the unsymmetrical retort-like shape of the discharge tube in Fig. 6. The bulb R, which is about 12 cm. in diameter, is connected on one side to the tube L, which leads to the absorption tube, and on the other side to the wide discharge tube E_1, (about 50 mm. in diameter). The latter is gradually constricted till it joins the tube E_2, which is about 10 mm. internal diameter. In the lower part of this tube are the exploring electrodes S_1 and S_2 for measuring the potential gradient. They consist of fine platinum wire which extends to the middle of the path of the discharge and have mercury cups which are connected with the long fine glass tubes J. The glass cups are provided at [686] the top with an enlarged part M, in which the amber pieces B are sealed air tight. These amber pieces are bored through and insulate the wire D leading to the electrometer. The object of this construction is to utilise the excellent insulation which the glass walls possess when the tube is immersed in liquid air.

The projecting part T is for the purpose of introducing various devices into the tube. In the figure, for instance, it is used for arranging a totally reflecting prism F so as to permit an observation of the distribution of light in the cross-section of the tube and also to integrate the intensity of the light in the entire length of the tube.

When observations are made at the temperature of liquid air, the tube is immersed in the liquid air to a depth of some centimetres above the prism.

The platinum ring Z serves as a starting electrode.

The following may be said concerning the electrodes. The cathode, which is the most sensitive part of the whole apparatus, has the peculiar form shown in the figure; the heating current is introduced through the mercury contacts Q. I have found that this method of construction not only makes the oxide cathode more durable than the usual methods, but the electrolysis of the glass which generates traces of gases is here prevented, as there is a piece of cold glass between the two wires. Copper wire spirals K are soldered to the two platinum wires and at the other small pieces of platinum wire connect with the platinum foil O. The latter is coated in the usual way with a layer of oxides of alkaline earths.

The anode is made out of a platinum vessel T shown in Fig. 7, in order to conduct away to the outside as readily as possible the not inconsiderable quantities of heat generated at its surface. In my last experiments I substituted for this platinum vessel a platinum tube (Fig. 8), which has the advantage of preventing impurities from gathering on the surface over which the discharge spreads. A further advantage in having the [687] anode a tube is that the discharge is spread out more uniformly over a part of the surface, whereas it is usually concentrated in the middle of that part of the anode which is at right angles to the axis of the discharge.

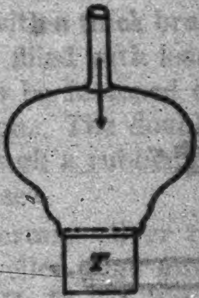

Fig. 7.

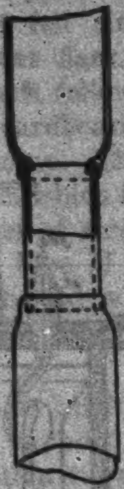

Fig. 8.

3. *The Cryostat.*

The cryostat, which not only enables the absorption tubes to be cooled to the temperature of solid air, but is also used for working with liquid hydrogen, is constructed on the principle of the cryostat of Kamerlingh Onnes[1] with of course the necessary modifications for the present purpose (Fig. 9). It consists of a wide brass

---

[1] H. Kamerlingh Onnes, Communications from the Phys. Lab. Leyden, No. 94f, 12, p. 32.

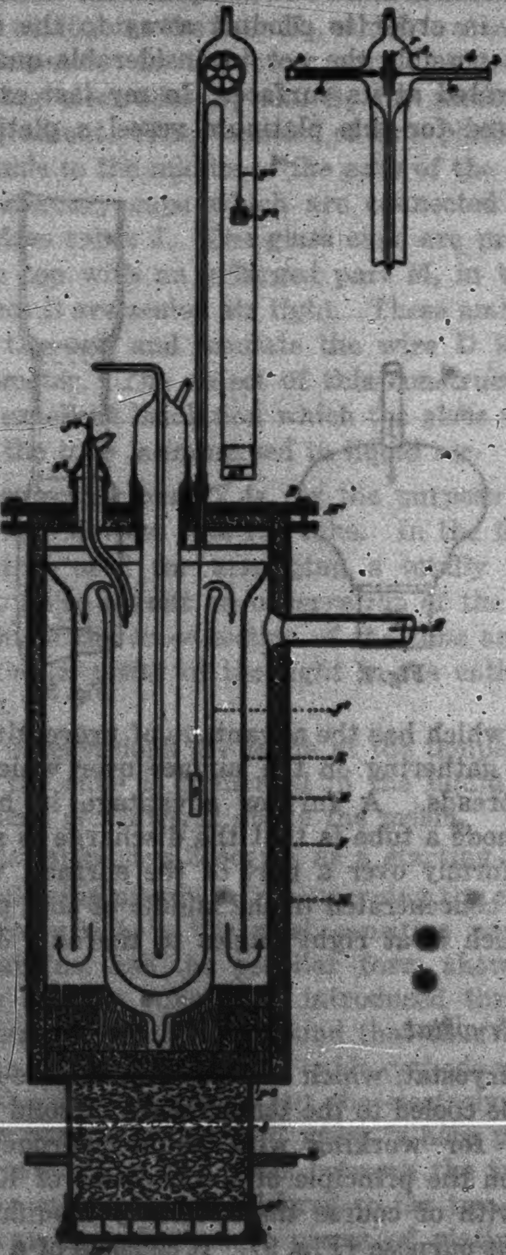

Fig. 8.

tube M, the inside of which is covered with a layer of felt, F, and a sheet of nickel, H. At the lower end the tube is soldered to a German silver tube S over which is stretched the rubber cap G_1. The latter is supported by a sieve-like plate, P. The German silver tube is filled with wadding and another sieve-like plate is provided on which are fastened a number of felt rings and a wooden base for supporting the Dewar flask D_1. The gases evaporating from the Dewar flask follow the path indicated by the arrows around the cardboard dividing wall through the tube E into the air pump. The cryostat is covered with a thick brass plate M, in which is a groove B, which is filled with lead. A number of screws enable the plate to be fastened down to the tube M in an air-tight fashion. The double walled tube J_2, which is inserted through a rubber cap G_2, is used to introduce the liquified gases.

The German silver ring R (B?) is inlaid with felt and its bevelled edge affords a firm support at the enlargement E, Fig. 4, for the absorption tube, which is likewise packed in with a rubber cap.

The float S, which, together with the cord F_1 and [689] weight F_2, serves to indicate the height of the liquid in the tube D_1, is placed in the glass tube which is closed with the rubber stopper G_3. The cross sectional view shows how the pully, r, in the glass tube s, is attached to the wire d, which passes through the tubes a, and is fastened to the brass discs b.

4. *The Electrical Measurements.*

The connection with the electrometer is made by means of the shielding arrangements shown in Fig. 10. As the distance of the electrometer from the discharge tube is frequently varied, it is convenient to so arrange the connections that their length can easily be varied. For this purpose the protecting tube consists of two parts R_1 and R_2, which are made to slide one over the other, while the actual connection with the electrometer

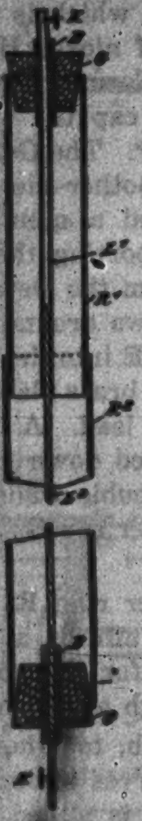

Fig. 10.

is established by means of the fine tube L_1, the wire L_2 which can be made to slide through it, and the binding screws K. The tubes R are closed by rubber stoppers G, through which pass insulating amber tubes B. In these latter the connecting parts L are fixed.

The potential differences were measured by a quadrant electrometer connected idiostatically. This was a Mascart-Carpentier instrument which was reconstructed for the measurement of the large potential differences (up to 400 volts) and provided with numerous alterations and amber insulation. The sensitiveness of the bi-filer suspension of platinum wire could be adjusted by varying the distance between the wires and by varying

the load. The damping arrangement, which is very im-
[690] portant where large couples are concerned, was a specially constructed air damping arrangement which enabled a periodicity to be attained in all cases.

Notwithstanding the unsensitiveness of the electrometer a careful electrostatic protection was indispensable mainly on account of the brush discharge from the connecting wires which occurred with high tensions. The electrometer, which was insulated, had to be set up inside an earth connected casing as the case of the instrument itself was at the potential of one of the exploring electrodes.

The galvanometer was a mirror instrument by Keyser and Schmidt (sensitiveness 10^{-8} amp.) and likewise carefully insulated. A series and shunt resistance enabled measurements in different ranges to be carried out.

Both instruments were read in an objective way so that both co-ordinates could be observed simultaneously on two scales one over the other.

As a source of current a high tension battery and a direct current generator were employed with like result. The resistances were metallic up to 11 megohms and from this up to 1,000 megohms amyl alcohol-cadmium iodide resistances.

5. *Description of Diagrams: Tables.*

The connection between current and potential gradient is communicated in the following diagrams and tables on the basis of the values of the current and the square of the potential gradient. The ordinates of the diagrams are the currents, whose absolute values in milliamperes are given when the corresponding ordinate is multiplied by the co-efficient 0.0572.

The absolute values of the abscissae are given by the following table in which the calibration of the elec-
[691] trometer is also communicated. This corresponds to the diagram of Fig. 11.

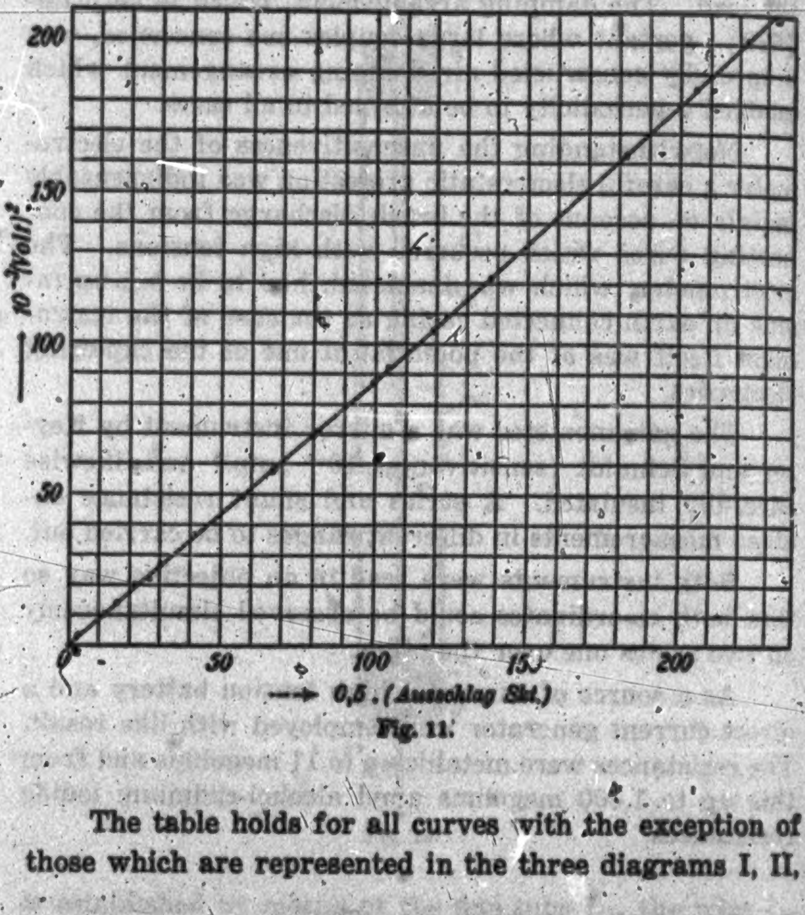

Fig. 11.

The table holds for all curves with the exception of those which are represented in the three diagrams I, II,

Deflection in Scale Divisions	Abscissae of the Diagram (Fig. 11)	$\frac{(\text{Volts})^2}{1{,}000}$	Volts

547	273.5	248.5	498.5

III; these were taken with a much greater electrometer sensitiveness, and their interest is of a more qualitative nature.

In the following tables the results of the observations are given which are graphically represented in diagrams 1-21. As regards the diagrams it should be remarked that, in order to facilitate comparison, the first curve on the left is referred to the actual system of co-ordinates, while each succeeding curve is referred to a system whose ordinate axis is displaced 10 scale divisions to the right relatively to that of the preceding curve. Finally practical considerations rendered it necessary to reduce the reproductions of the curves in the proportion of 2:5.

IV. RESULTS OF EXPERIMENTAL OBSERVATIONS.

1. *Relation between Potential Gradients, Current Density and the Vacuum.*

Even during the first potential measurements by means of sounds when the methods of evacuation had not yet been developed to the same extent as in the course of time, there was found to exist besides various irregularities and phenomena that always appeared in different form, a definite relation which could always be reproduced. It was found that when the discharge tube had been subjected to a proper previous treatment and the degree of vacuum mentioned in the introduction had been obtained, the relation between the current J and the potential gradient v could be expressed by (1)

$$J = a v^2 + b$$

where a and b are constants that will be more fully interpreted later.18) The condition for this law was, besides the one already mentioned, namely, that the proper degree of evacuation must be reached, that J should not have too small a value—with a tube diameter of 10 mm. about 1 milliampere. For current values greater than this, this law held so long until the heating of the glass walls in virtue of the discharge caused a marked addition to the pressure of the gas in the tube, because since an increase in the pressure of the gas caused a decrease in the potential difference for constant current, a heating of the glass walls caused a in equation (1) to increase and this corresponds to another vacuum. b which was held very small for the gas pressures dealt with in the earlier investigations could be neglected as a first approximation in these.

Whatever was said about the quadratic law holds for the better vacuum that could now be obtained with
[700] the help of newly installed equipment. Also here every reduction in the gas pressure up to the limiting region to be considered later on causes a diminution in

a. Furthermore, there are three peculiarities of the characteristic that always were found to exist. We shall, in order to avoid repetition, briefly state these here.

(a) Provided that we deal with variation in gas density within the region of the vacuum here investigated, the minimum current from which on the equation (1)

$$J = a v^2 + b$$

holds is always smaller for the larger pressure than for the higher vacuum.

(b) The b increases with a decrease in gas density, but generally remains small in comparison with the discharge current that came under observation.

(c) With the smallest currents that were observed current densities that lie very far below the region mentioned under (a) the potential gradient and the current strength cannot be connected by a definite relation, as can be seen from the lower parts of the diagrams where the points are scattered.

Contrary to the parts of the curve that strictly follow the equation (1), there were other parts for small currents which in the initial experiments were not so good. These parts, as already pointed out under (c), were not only different for different apparatus, but even for the same tube they varied. It often happened that it was not possible to get a satisfactory series of observations for this part of the curve. Diagram 1 gives the curve for a tube made out of Thueringer glass. As abscissae are given the square of the potential gradients and as ordinates the currents. The diameter of the tube [701] was 14 mm. It is seen the uniform upper part of the curve, which indicates a definite relation between current and potential gradient, is preceded by a curve which is different for increasing and decreasing currents, similar to what is found in the ordinary discharge of Geissler tubes, that the potential gradient decreases with increasing current. Besides this, there is a part of the curve for the smallest currents which indicates a potential gradient which is relatively very high. Diagram II

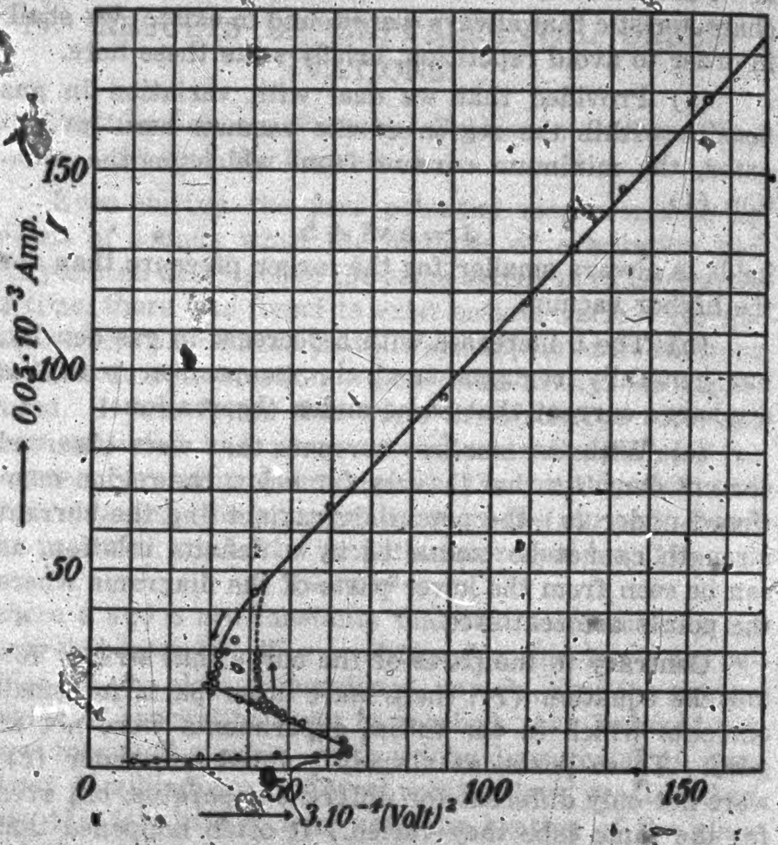

Diagramm I.

shows a part of the curve which is analogous to the last mentioned, and one which is quite marked here, but was only indicative in the tube of Diagram I. This part shows relatively high currents for small v^2. In the second diagram, however, the part of the curve which [702] indicates an increase in potential for increase in current was too unstable to be measured. Diagram II represents the results obtained with a tube made of Jena glass.

In the course of the investigation it was found that the lower irregular part of the characteristic became smaller and less marked, the more the walls of the vessel were freed from absorbed gases. This could probably

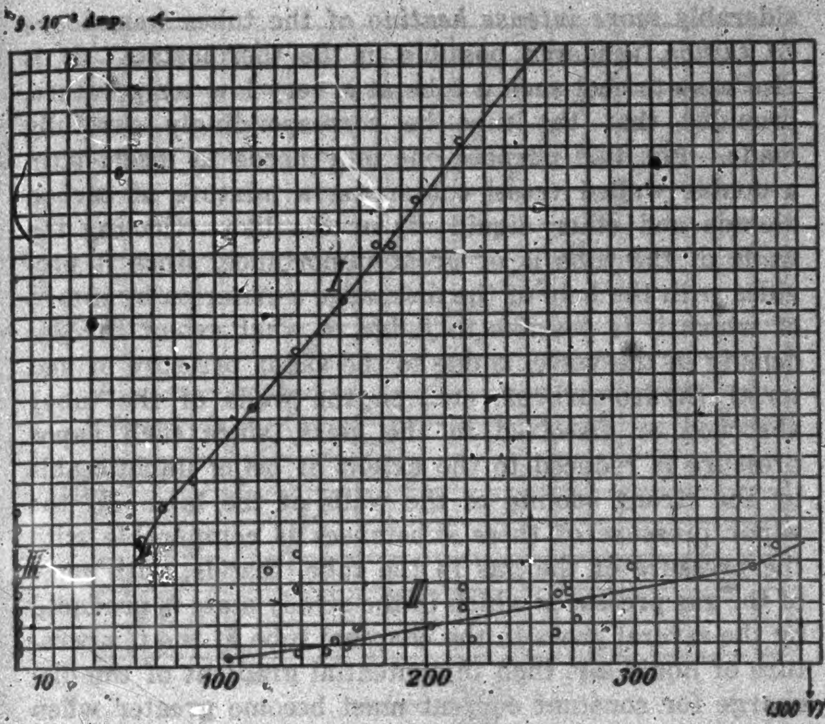

Diagramm II.

be taken to indicate the transition stage between discharge at higher pressures and the discharge in the vacuum worked with here. Since the separation of the important from the unimportant (insulation faults, gas peculiarities, residue formation, uncleanliness of all kinds) caused great difficulty due to the inconsistency [703] of the phenomena, the plan was adopted here to better the vacuum as much as possible in the hope of finding a uniform characteristic by producing well defined conditions and perhaps on the basis of an insight thus obtained to critically repeat prior observations.

For this purpose the tubes were thenceforth made of Jena glass to avoid impurities due to the sealing in with lead glass. Furthermore, I abandoned the original type of tube whose main expansion was in a horizontal plane and designed a form of tube which I referred to in Part III as the vertical type. Consequently a considerably *more intense heating* of the tubes was, *above all things*, rendered possible in the thermostats. It is also easy to cool such a tube at a very low temperature, provided that the tube be correspondingly carefully made. For this purpose one only needs to insert it in a double walled vessel containing a mixture of carbon dioxide and ether, liquid air or the like. Cooling the walls of the tube is of great importance, since it provides with the help of the discharge a criterion by means of which it is possible to judge to what extent the gas density in the vessel is due to the vapor pressure of material (hydro-carbons, etc., on the walls of the tube) absorbed or dissolved in the glass, since such vapor pressure is reduced to the extent of being unnoticeable by the strong cooling of the walls of the tube. If the vapor pressure of these substances is comparable with the pressure of the gas in the tube, that is, with some of the gas pressures which in the steady state is produced by the several gases in the charcoal tube at the temperature of liquid air, then the potential gradient of the discharge for constant current must become greater when the tube is cooled than in the ordinary case in which the tube hangs freely in the air and is strongly heated by the discharge current.

In fact it was found in the first experiments that by cooling the tube to —180° the potential difference [704] between sound wires was almost double. After that the thermostat was improved and given the form described above. The result is given in diagram 1 (continuous current) in which case the tube hung freely and was heated by the discharge. After long continued discharge this curve went off into the dotted one, which gave higher voltages for the same current, thus indicating a better vacuum. On the following day the curve given in diagram 2 was taken, which corresponds to a still better vacuum obtained with long continued absorption and discharge. The dotted part of the curve represents conditions in which a strong discharge caused so much heating (up to about 250°) that an increase in

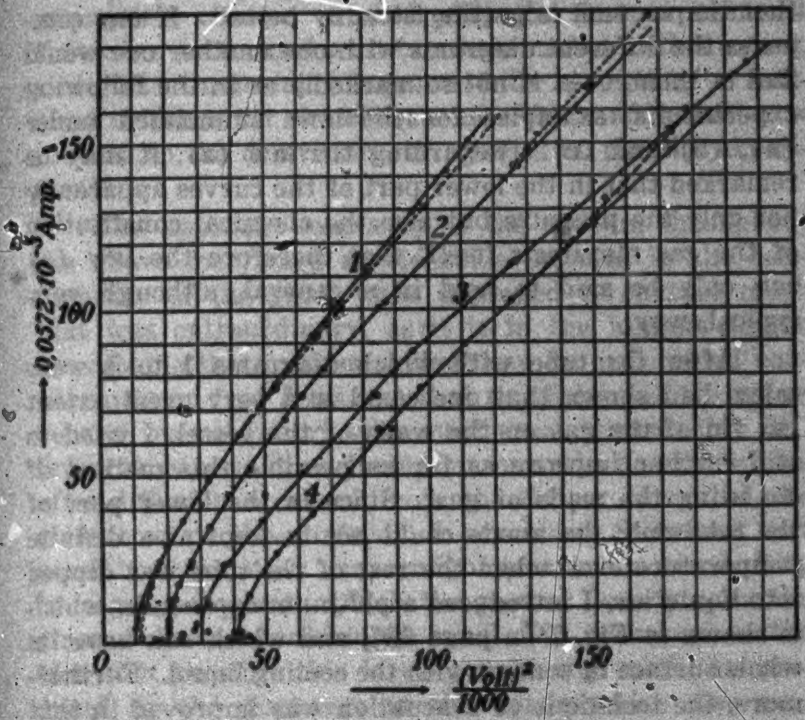

Diagramm 1—4.

vapor pressure on the glass walls becomes noticeable. [705] Diagram 3 shows a curve taken when the tube was dipped into the liquid air. In this case there is no deviation indicating higher pressure such as is given by the dotted line of diagram 2, even for higher potentials and large currents. The dotted curve gives the characteristic directly before immersion of the tube in liquid air. One sees that the improved method of heating the tube resulted in a very great improvement in these experiments over those in which the potential gradient was doubled as a result of cooling.

Diagram 4 gives a characteristic that was taken the following day without cooling. The broken curve has the same meaning as that attached to diagram 2; the dotted part gives for comparison the relation observed on the previous day without cooling. One sees that the vacuum is getting steadily better. If one compares the different diagrams with one another one would find in them, even if not so markedly as in the following experiments, examples for the laws enunciated under (a), (b) and (c). Regarding the law (a), it may be remarked that in the lower part of the curves apparently not only the pressure but also the chemical constitution of the gas manifests itself, that therefore the law (a) can only be said to hold in a general, although very typical, way.

After the tube with which diagrams 1 to 4 were taken had shown that one could to a very great extent get rid of the gas on the walls of the vessel, I tried to still further improve as far as possible this method of denuding the walls of gas. Since in the lower part of the tube only the anode could not be kept at a definite temperature even when the rest of the tube was dipped into liquid air, I introduced a platinum cap anode, which is shown in Fig. 7 on page 687, and which can have its whole surface in contact with the cooling liquid. Furthermore, the technique of evacuation was improved in that the method of pumping and the arrangement of the absorption vessels described on page 682 were used. Working now on the principle that in the earliest possible stages of pumping a part of the tubing was kept uninterruptedly at a very much lower temperature than [706] the discharge tube, I reached a degree of purity of the glass walls for which the part $J = a\,v^2 + b$ remains unchanged even for great temperature changes. It was, in fact, possible to proceed on the above mentioned principle of obtaining the vacuum even in the case of investigations lasting weeks at a stretch, since the liquefaction installation which had meanwhile been erected in the Institute gave large quantities of liquid air very reliably. In this way it was attained that, with a temperature change from about + 200 degrees corresponding to an uncooled tube through which a discharge was passing, down to — 185 degrees in a bath of liquid air, the coefficient of equation (1) underwent no perceptible change. I shall skip the first experiments that were performed with tubes evacuated to this extent, since later material (diagrams 5 to 14) will give sufficient evidence for the above contention, and I shall now proceed to the description of a series of parallel experiments.

The apparent constancy of the vacuum throughout the above mentioned considerable interval in the temperature of the glass walls appeared to contain much that was extraordinary, as it is in the highest degree improbable that a glass surface can be maintained continuously so free from gas that no change in the vapor density over it occurs with such great temperature differences, especially as during many weeks no appreciable after-diffusion occurred from the deeper layers of the glass toward the surface. I concluded therefore that possibly some other cause might produce a gas density by comparison with which the partial density over the glass wall was vanishingly small. So I arrived at the idea that possibly this large gas density might be produced by the discharge at the anode which was perceptibly heated.

In order to test this question experimentally five pot-shaped anodes of platinum were sealed into a glass vessel in the form of a very oblate ellipsoid (Fig. 11). The middle one was not inlaid but in each of the other four was placed an exactly fitting pot made of foil 0.3 mm. in thickness of nickel, gold, German aluminum and [707] English aluminum respectively. The inlaid pots had their edges turned over to prevent traces of the discharge from leaving the upper edge of the platinum. The two sorts of aluminum were chosen because of the well-known experience of Roentgen tube makers that German aluminum contains more sodium and consequently gives off much more gas (hydrogen) [19)] under the influence of the vacuum discharge. It is just *this* property which renders it more suitable for use in Roentgen tubes than the metal of English origin.

Everything was therefore so arranged as to make

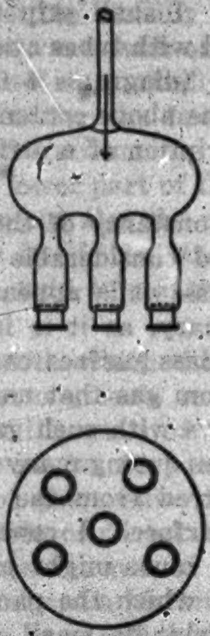

Fig. 11.

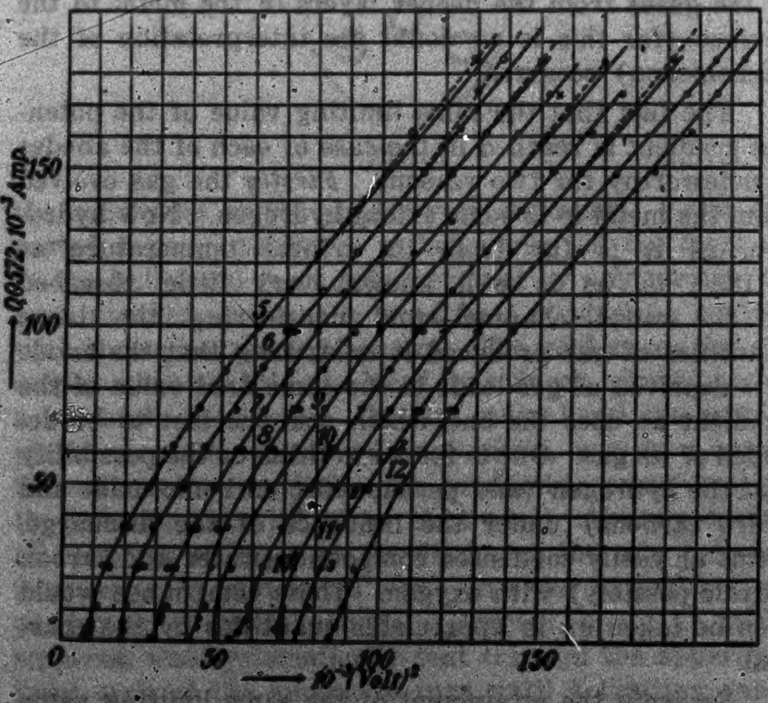
the conditions at the anodes very different. I also expected a great difference in behaviour, all the more so as the individual inset pots were not by any means—as was intended—in equally good heat conducting contact with the surrounding platinum. The gold anode for example, when slightly displaced by a knock, glowed under a moderate discharge. On the other hand the middle platinum anode which was not inlaid, was in a much more favorable condition for conducting away heat to the exterior than the other electrodes. Already during the removal of gases by the discharge the tube behaved in an entirely unexpected way. In order to enable comparison to be made a definite current, about 11 milliamperes, was systematically sent through the apparatus from each of the anodes in turn until a limiting value of the potential gradient was reached which remained unchanged for a considerable time (15 minutes). Now, contrary to all expectation, the same limiting value re-
[708] sulted for each anode, one after the other, as

for its predecessor which had just been deprived of gas, although different times were necessary to attain it. The time required to deprive the platinum, English aluminum, nickel and gold anodes of gas was 40 to 100 minutes in each case while the German aluminum anode required over 3 hours to reach the limiting value. It is of interest to note that, after the tube has been deprived of gas for the first time and is then left for 24 hours without any discharge, the limiting value does not set in immediately the discharge is switched on again, but some time, although a very much shorter period, must elapse before the limiting value is again reached. This can be repeated for several days, but the periods necessary to get rid of the gas get shorter and shorter till at last a stage is reached in which no after-diffusion of the gases from the deeper layers of the metal to the surface (for this is no doubt the interpretation of the phenomenon) occurred.

The fact that the same limiting value of the potential gradient is reached in the case of each of the anodes is noteworthy for two reasons. *Firstly* the gas evolved from the metal is to some extent hydrogen. Now hydrogen; as it is far from its critical temperature at —185°, is, as is well known, very little absorbed by the wood charcoal—and considering the large quantities of gas produced it is striking that the anode *first* deprived of gas leads to the same final value of the gradient as does the one which was the last to be denuded of its gas. One is forced to think of the possibility that the hydrogen (and perhaps also carbonic oxide and hydro carbons) under the influence of the discharge, forms an easily condensed compound (water and carbon dioxide possibly) with oxygen. These compounds would then be taken up in appreciable quantities by the charcoal.

Secondly the attainment of the same limiting value independently of the material of the anodes is also remarkable because, if we were to take this limiting value as a measure of the vacuum, it would amount to saying

[709] that the stationary equilibrium between the evolution of gas from the anode on the one hand and the gas absorption by the charcoal on the other leads to the same limiting value independently of the constitution of the electrodes. When we consider the great change in the evolution of gas which is produced by the slightest change in the materials used in the construction of vacuum tubes generally (also Roentgen tubes) we are forced to look for some way of avoiding the last conclusion, especially when we remember the large quantities of energy liberated at the electrodes in my experiments. One would first think of the possibility that the vapour density given off from the glass walls is great in comparison with that given off from the anodes. Now



Diagrams 5—12.

it follows from the diagrams that the vapour density over the glass walls is not perceptible at all. The diagrams 5, 6, 7 and 8 show the characteristics taken on the 10th November 1909 with the nickel, platinum, English aluminum and gold anodes respectively. It will be seen that these curves in the part $J = \alpha v^2 + B$ correspond [710] with one another exactly as regards α, that is they have all the same inclination. In the case of the last curve, Diagram 8, the vapour pressure over the glass wall has been reduced to such a degree by the preceding exhaustion that the same constants α and B still hold with heavy discharge currents, whereas the preceding diagrams show deviations at the corresponding part in the sense of an increasing pressure. In so far as the differences in B do not lie within the limits of error mentioned below (p. 724) it can be concluded from them and especially from the course of the curves for small currents (cf. (a) and (b) p. 700) that notwithstanding the agreement for big currents, the vacuum was not the same in all the experiments; it was best for instance in the case of the English aluminum. On the following day the determination in the case of the last mentioned anode was repeated (Diagram 9) and the German aluminum anode was freed from gas and the characteristic $J = \alpha v^2 + B$, which was likewise in agreement with the others, taken (Diagram 10*).

On the next day the investigation of the tube in a bath of liquid air took place. It will be seen from the carefully determined curves 10 and 11, and also from the more widely separated measurements which give 12, 13 and 14 that there is a complete agreement, not only with one another, but also with the curves 5-9 in the rectilinear part, and only in the parts corresponding to smaller currents was it just possible with the help of (a) (p. 700) to recognize in some cases an improvement of the vacuum as compared with the process of exhaustion with the discharge and no cooling. It follows that the constancy of the measurements was not due to the vapour density over the glass wall far exceeding the evolution of gas from the anodes. There remains therefore a last possibility, if we question the objective uniformity of behavior of the anodes, namely that the gases absorbed by the charcoal give rise to a total gas density which is great in comparison with gas densities from other sources.

It was therefore time to investigate whether a lowering of the temperature of the charcoal would produce an appreciable rise in the potential gradient.

As the liquid hydrogen reducing plant of the Insti-[711] tute was at the time being extended and reconstructed I had, for the time being, to be content with cooling the absorption vessel to the temperature of solid air. For this purpose, after a number of experiments with the tube just described which were not quite free from objection, and to which I shall refer again later, a tube of the ordinary form, but with a cylindrical anode (cf. Fig. 8, p. 687) was evacuated with special care for

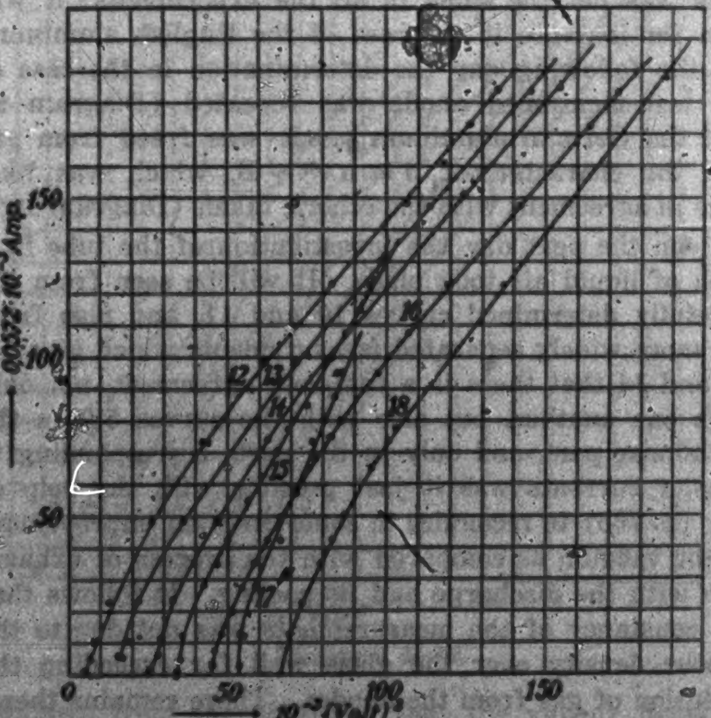


Diagramm 13—19.

days on end, so that its characteristic in a bath of liquid air was not to be distinguished from that obtained without cooling. Then the liquid air around the absorption vessel was allowed to vaporise under a pressure of 10 mm. of mercury for 4 hours at a time, at first with the tube free in the air and later cooled with liquid air. The result was that not the slightest change could be perceived, not even when the discharge tube was run for [712] hours on end with a heavy discharge current during the experiment with solid air, so that the conditions were favorable for still further freeing the walls of the discharge tube from absorbed gases.

Diagram 19 shows the characteristic when the absorption tube is in liquid air (about —185°) while the discharge tube is not cooled.

Diagram 20 shows the characteristic of the same tube, indicated by circles, where both discharge tube and

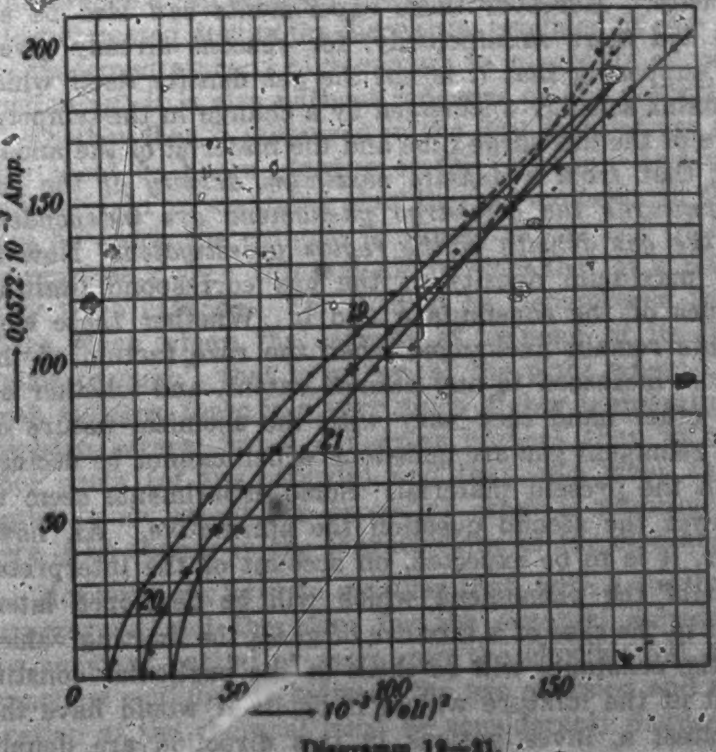

Diagramm 19—21.

absorption tube are cooled to — 185° and then the curve, indicated by crosses, for which the absorption tube was in solid air (about — 220°, as with the small pressure of 8-10 mm. the oxygen is also almost on the point of solidifying) and the discharge tube again in liquid air. [713] Most of the points coincide, since, as on other occasions, the function was taken by giving the current a definite value and then reading the electrometer deflexion. There is no perceptible difference here. As however a lowering of the temperature by about 35° must at these low temperatures[20)] considerably increase the absorption by the charcoal, it follows also that the lowering of the gas density has no influence on the conduction of the current in the high grade vacuum within the range of current strengths investigated.

For the previous experiments had shown that the other causes present do not produce any perceptible gas density. Moreover these experiments can also be explained more satisfactorily, for reasons already given, by supposing that it is not the gas density itself which remains sensibly unchanged by a change in the temperature of the discharge tube and the material of the anode, but that *from a definite maximum density of the gas downwards the discharge phenomena are independent of the gas density in the region investigated.* Now to the maximum density of the gas correspond limiting values of the constants a and b. Whether these constants remain unchanged when the rare faction of the gas is increased to any desired extent, and whether on the other hand they vary with the chemical nature of the remanent gas are questions which cannot be decided with the present material. Some experiments seem to answer the second question the affirmative. As, however, it is to be expected, on account of the interpretation of the phenomena which will be developed later, that in the case of a mixture of gases the limiting values of the constants will be those of the particular constituent of the mixture which, if by itself would have the greatest a, investigations in this direction are doubly difficult to carry out and can only yield reliable results on the basis of an extraordinarily comprehensive amount of material. For it does not seem to be easy, on account of the probable oxidation of all the remanent gas mentioned on p. 708, to have, in a steady state, any gas, and yet a strictly defined gas, through which to pass the discharge.

It might possibly be thought that the continuous [714] emission of gas from the oxide cathode is sufficiently great to completely push into the background all the factors dealt with above which influence the gas density. This idea, however, is contradicted by every day experience, for it obviously means that the potential gradient must necessarily vary greatly with the constitution of this cathode.

Now as a matter of experience it not only makes no difference at all whether the cathode is very strongly or feebly heated during the discharge, provided of course that its temperature is high enough to ensure its proper functioning; it is also without influence on the potential fall whether that is measured in the first hour of use or after about 60 hours glowing of the cathode. And we shall be right in assuming that the gas emission in the cases in which the cathode is almost at the end of its life must be a very different affair from that of a relatively fresh cathode. For it must be remembered that at the place where the cathode at the end of its life "burns through", that is to say, at the place where the break appears, there is a very much higher temperature (perhaps several hundred degrees higher) than in the other parts (of the cathode) and that even when thus heated to an extent for exceeding what is admissible, there is no change in the characteristic of the discharge.

Moreover we have to consider that, with a constant temperature, and therefore for the eventual existence of a constant partial pressure over the glowing foil, the dynamical equilibrium between the gas emission and absorption at the charcoal must be considerably displaced according as the cathode is a fresh one or has been in use for many hours, since the velocity with which the gases are given off must diminish in course of time.

If the evolution of gas from the same cathode is to be regarded as changing in course of time, we should expect it to be very different indeed with different cathodes as their condition varies very appreciably from one case to another. Notwithstanding this, when a new cathode is introduced into a new tube no change can [715] be observed in the limiting value of the potential drop (gradient). And even with *different discharge tubes* we arrive at *exactly the same limiting value*[21)] provided we take into consideration the way in which the characteristic varies with the geometrical features of the tube, on the basis of the laws given further below. So the behaviour of the cathode is a very important reason for the assumption of the existence of a maximum value of the gas density from which downwards the potential drop remains unchanged rather than one which is in conflict with this assumption.

Finally, when the temperature of the absorbing substance is lowered appreciably, an essentially different dynamical equilibrium of the gas density must set in between the evolution of gas at the cathode on the one hand and the absorption of gas at the charcoal on the other. But this, as we have seen, produces no change at all in the characteristic.

The diagrams 15, 16, 17, 18 as well as 21 are rather more distantly, though still very closely, related to the subject discussed above. The first four diagrams were taken with the tube with 5 anodes, in connection with the experiments already described, after intentionally violating the principle of exhausting mentioned on p. 681;—that a portion of the connecting tubing should always be maintained at a much lower temperature than the discharge tube. This was done by keeping the absorption vessel for a time, about an hour, at room temperature. Curve 15, taken after this, shows, when compared with diagrams 5-14, that a considerable contamination of the glass walls was immediately caused. Curve 16, which was taken with the discharge tube immersed in liquid air, shows that the cooling completely dispels the effect of the impurities and gives the characteristic the form it has in the case of an uncontaminated tube which is not cooled. At the same time the curves 15 and 16 furnish clear illustrations for the laws (a) and (b) p. 700.

[716]

It may be remarked by the way, that, with curve 15, even with a moderate discharge only, under which the glass walls would in other cases show no trace of the sodium spectrum, the emission of a line of an extraordinarily great intensity coinciding with the sodium D lines was observed with a simple spectroscope. As such a spectral phenomenon does not appear with uncontaminated tubes, that is with small gas densities, not even with much heavier discharge currents, and as it is probably to be ascribed to the formation of diffuse canal rays, this observation may provide some insight of fundamental importance into the formation of canal rays. As simultaneously with the appearance of the D line and the contamination of the tube an intense hydrocarbon spectrum appears it is natural to suppose that a casual connection exists between the two phenomena. This fact may be related to one observed by J. J. Thomson that in high vacua canal rays always have a ratio of charge to mass corresponding to hydrogen. This way of explaining Thomson's experiments seems all the more likely as no sufficient precautions were taken in his experiments to get rid of the partial pressure of hydrocarbons over the glass walls.

Diagram 17 was obtained after heating the walls of the absorption tube at room temperature for a longer period. A further deterioration of the vacuum as compared with curve 14 will be recognized. Curve 18 was taken after this with the discharge tube cooled in liquid air. The vacuum was now so badly defined that even this intense cooling did not quite suffice to bring the gradient (drop) back to the old limiting value. At the same time a preliminary experiment of cooling the absorption tube by solid air was carried out, the result of which did not differ appreciably from curve 18. On account of the contamination and the consequent appreciable vapour density over the glass walls this experiment is indeed not any more convincing and is therefore not mentioned again.

[717]

Curves 17 and 18 also furnish illustrations for the laws (a) and (b) p. 700. Diagram 21 was obtained with the same tube as diagrams 19 and 20 under circumstances similar to those under which curves 15 and 17 were obtained with the tube with five anodes. We also find illustrations for laws (a) and (b) in comparing 21 with 19 and 20.

In order to get the law of the lower part of the characteristic, that is, of the part which extends from $J = 0$ to the region where $J = a v^2 + b$ is valid, we may use the curve of diagram 20 in the following way. A parallel displacement along the horizontal axis is carried out so as to make the curve pass through the origin of coordinates. This happens when v^2 is replaced by $(v^2 - 11)$. Logarithms are now taken of $(v^2 - 11)$ as well as of J for the whole curve. If we, for the sake of convenience, subtract 0.70 from log J in the following table and introduce therefor log J — 0.70, and if we further multiply both this quantity and log $(v - 11)$ by 100, we obtain the following:—

I	II	III	IV
1	5	0	0
2.5	10	40	30
4.5	15	65	47
6.8	20	83	60
9.5	25	98	70
12.6	30	110	78
17.2	35	124	84

19.7	40	129	90
23.7	45	137	95
26.8	50	143	100
34.8	60	154	108
42.9	70	163	114
51.9	80	171	120
62.0	90	179	125
72.0	100	186	130
92.5	120	197	138
114.0	140	206	145
135.0	160	213	150
156.0	180	219	155
176.5	200	225	160

Column I contains the quantity 10^{-3} (volts)$^2 - 11$
" II " " " 0.0572×10^{-3} Amp.
" III " " " $10^2 \log_{10} (v^2 - 11)$
" IV " " " $10^2 \log_{10} (0.0572 \times 10^{-3}$ Amp.$) - 0.70$

[718] Columns III and IV are represented graphically in diagram 20a. The points from the origin of coordinates to the bend indicated by the arrow undoubtedly lie on a straight line which corresponds to the curved portion of diagram 20a. The equation of this straight line is if we take as a first approximation for the tangent of its angle of inclination to the horizontal axis the value $\frac{3}{4}$, $\log J - 0.70 = \frac{3}{4} \log_{10} (v^2 - 11)$
and therefore

$$J = 10^{0.70} (v^2 - 11)^{3/4}$$

The part of the curve above the bend indicated by the arrow corresponds to the straight part of the curve of diagram 20, $J = a v^2 + b$, and is consequently likewise a straight line. A superficial examination might give the impression that this part of the curve is determined by too few points. In reality the
[719] accuracy of its determination by far exceeds that which can be reproduced by the method of diagram 20a, as the curve corresponding to the anti-logarithms of the coordinates is itself a sharply defined straight line.

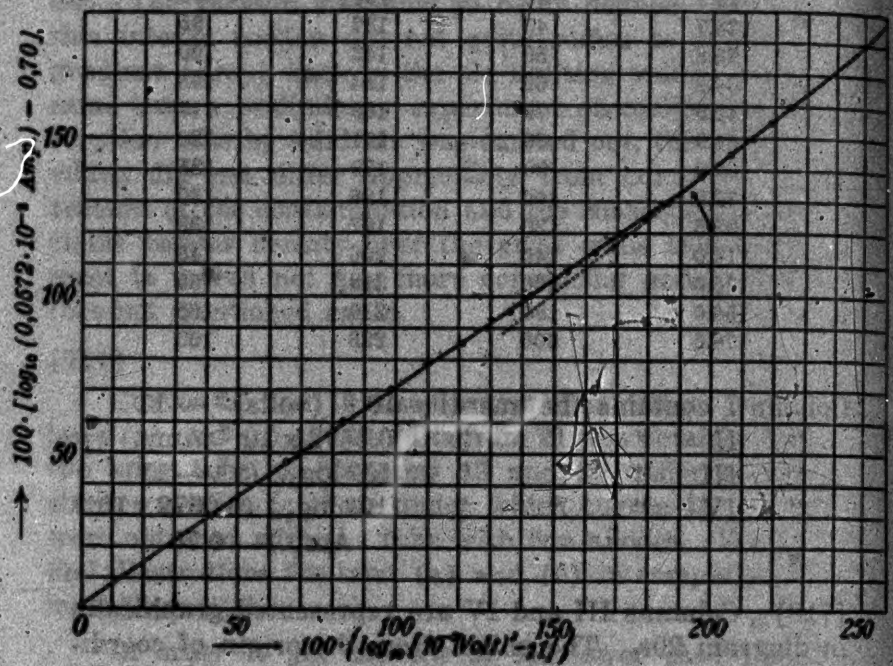

Diagramm 20 a.

The bend which has been mentioned, therefore possesses undoubtedly a real meaning, namely that in its neighborhood the exponent of the potential drop (gradient) in the characteristic increases by about 25% of its initial value.

More exactly formulated; *the characteristic consists of two parts. In the first part the potential drop (gradient) increases as $J^{2/3}$ in the second as $J^{1/2}$. In both parts the connection between J and v is represented simply by a power.*

A few remarks may be made here concerning some diagrams which are apparently determined by few points, and also concerning the general accuracy of the measurements. For technical reasons one generally endeavours to work as quickly as possible. For if we intend to carry out with an apparatus a long series of connected measurements we have to take into consideration that the life of a tube and especially that of the cathode is limited. The circumstance that each new apparatus not only causes expense but also much trouble and loss of time during exhaustion and getting ready for measuring is not without importance. Of necessity therefore a method of working must be chosen which, before all things, leads as rapidly as possible to the end in view. Setting the current for definite values and observing the resulting electrometer deflexion is obviously such a method. It is a relief to the observer, whose attention is in any case greatly taken up by the whole apparatus, if the apparatus is frequently set for the same few well marked points in preference to taking many observations in a continuous way one after the other, especially as any disturbances are at once noticed in this way and can be removed. Therefore those curves which are determined by less numerous points are not of less value, at any rate for our present purposes, than some of those determined by continuously distributed points.

[720]

As regards the accuracy of the measurements, it is, as the diagrams prove, generally very satisfactory, especially when we consider that every disturbance in the exterior circuit (especially in the running of the high tension machines) directly affects the *first power* of the potential drop between the terminals of the tube, while it is *the square* of the potential drop (gradient) which is measured and represented in the diagrams. It can be seen from some of the curves that the accuracy could be uniformly and considerably increased in case of need, though this, as has been said, would not be of utility for our present purposes—for the constancy of the phenomena is in itself very great. It would then be necessary of course to relieve the actual observer from the supervision of the working of the apparatus, and, especially, to arrange for the high tension machines to be driven always from the battery of the Institute during measurements. As a rule the measurements last too long for the capacity of the Institute's battery to suffice;

so that it is preferable to work with the town supply generally—which naturally reduces the accuracy of the measurements—rather than that the attention of the observer should be taken up by frequently switching on and off the current driving the high tension machines.

2. *Influence of the Geometric Conditions on the Potential Gradient; Spectral Observations.*

Along the discharge tube the potential gradient is distributed as follows: At the oxide cathode it is a few volts—according to the condition of the cathode. An increase in the vacuum over that which is usually obtained with air pumps causes no change here. The proof of this is given, as is easily conceivable, by introducing an exploring electrode in the neighborhood of the cathode.

Along the axis of the discharge column the potential drop, within the limits of validity of the law $J = av^2 + b$, is linearly distributed. With bigger gas densities, that is at the beginning of the region of investigation, it increases in the direction from the cathode to the anode and when the vacuum is improved to some extent it very soon attains a linear distribution—the [721] cross-section being supposed constant, of course. This can be proved simply by a row of exploring electrodes placed one behind the other, this fact appears to furnish the justification—which at the outset is not at all obvious—of speaking of a positive column in the extreme vacuum.

At the anode there is no exceptional drop in the gradient, at least as long as the anode is sufficiently large.

The determination of the distribution of potential gradient perpendicular to the axis cannot be carried out with the same method. If, however, the tube with the totally reflecting prism (Fig. 6) be used there is seen, as long as the vacuum is not so good that the characteristic remains unaltered, a well marked thread along the axis of the tube, which emits the cathode ray band spectrum of oxygen besides the carbohydrate and perhaps also the hydrogen spectra. One would be inclined to conclude from this that the current density is by far the greatest in the immediate neighborhood of the axis.

As the vacuum gets better, however, this thread shrinks together more and more and finally vanishes,—and with it every trace of a discontinuous spectrum vanishes; at least as far as can be seen with an ordinary spectroscope. There only remains then a uniformly distributed luminescence, which gives a continuous spectrum. This fact and the law derived below, that the characteristic is determined by the current and is independent of the dimensions of the tube speaks against the assumption that the current density is greatest in the center of the tube. On the contrary, the inner discontinually glowing thread seems rather to be a phenomenon closely related to striction canal rays, which also is connected with the apparent emission of the D-light (p. 716) and then vanishes in very high vacuum, in which obviously the possibility of the existence of canal rays is greatly reduced.

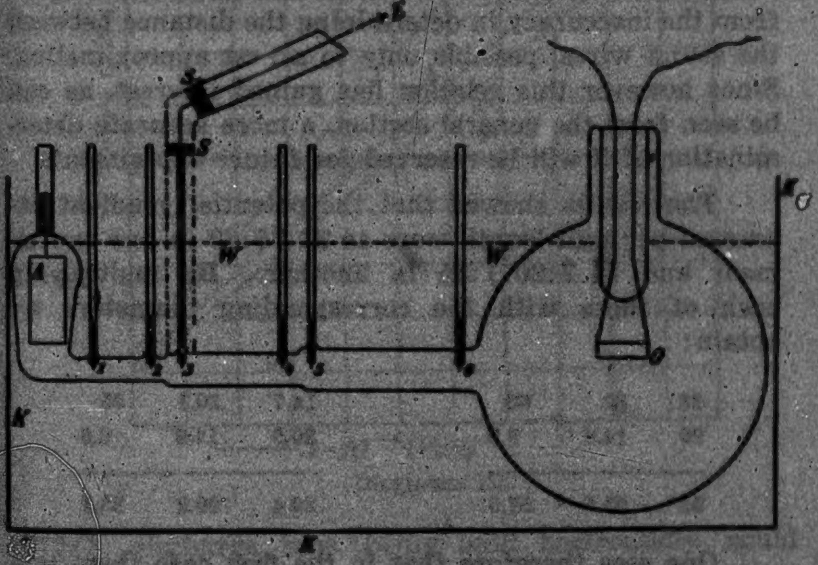

Fig. 13.

The dependence of the potential gradient on the cross section of the current path, for constant current, [722] i.e., on the current density, was studied with the horizontal type of tube shown in Fig. 12. Three cross sections were used. The diameters (20.0, 14.6, 9.5 mm.) were measured after the tube had been taken apart,[23] and so also the distances between the sounds. This was done in order not to introduce errors due to irregularities in the glass walls. The distances between the sounds (630, 500, 315 mm.), were so chosen with the help of previous experiments, that the potential difference between the several pairs was about the same for the same current, so that the potential difference between them could be determined with the same sensitivity of the electrometers.

It is to be remarked that on account of the wires sealed into the tube and of the changes from one diameter to the other, the tubes were not perfectly cylindrical. Moreover, the diameter of glass tubes about 20 mm. [723] inside diam. varies about 5 to 10%. Consequently the determination of the dependence of the characteristic on the cross section of the tube is, apart from the inaccuracy in determining the distance between the sound wires, possible only to a first approximation. Since however this relation has gained interest, as can be seen from the general section, a more accurate determination of it will be reserved for future experiments.

The results showed that the potential gradient expressed per unit length were as 28:36:60 in one experiment and 14.7:20.1:35 in another. By multiplying each of these with the corresponding diameters we obtain:

28	36	60
20	14.6	9.5
56	52.5	57.0

14.7	20.1	35
20.0	14.6	9.5
29.4	29.2	33.1

One sees therefore that in the first case there is a very good constancy and in the second, in view of the above mentioned sources of error, a marked constancy. Although I give preference to the first row of measurements, which were taken in the quickest possible succession, still the second may also be taken as representing a large number of observations.

Expressed verbally this result is: The potential gradient is, for constant gas density and current, inversely proportional to the diameter of the tube. If the potential gradient for two tubes of radii r_1 and r_2 be v_1 and v_2 then:

$$v_1 : v_2 = r_2 : r_1$$

It would be interesting to make a comparative determination of the current-voltage characteristic for tubes of different cross sections. Since, however, the

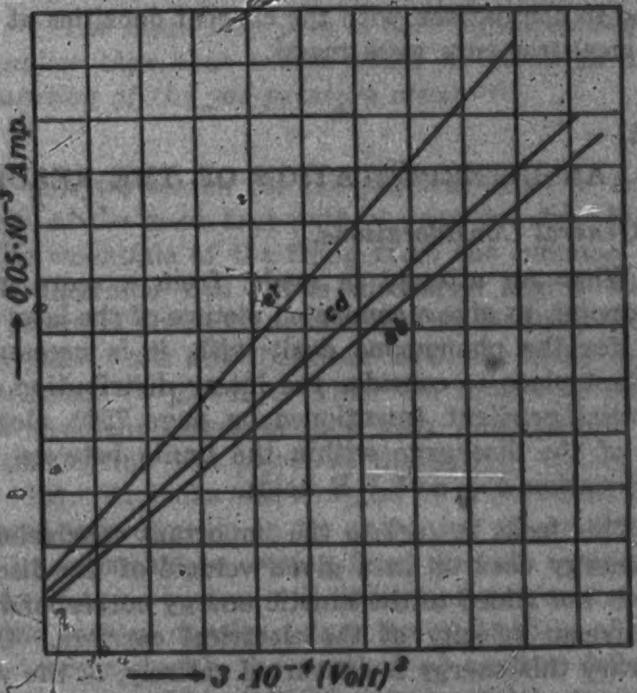

Diagram III.

[724] discharge tube, being built horizontally, could not be heated high enough in the furnace, and conse-

quently the curves did not remain constant during a longer discharge, they are not adapted to a closer discussion in this direction. However, a rough diagram may be given here showing curves which approximately obey the equation $J = a v^2 + b$, and which have been extended to intercept with the J axis to show how b is changed by a cross section. As is seen, every change in the zero point strongly modifies b and this is another source of error which makes it impossible to obtain an exact law by which b can be determined.

One thing is certain, viz., that b increases markedly with increasing diameter of the tube.

The above mentioned errors in b do not exert much of an influence on the measurement of the variation and potential gradient with the current, since it can be neglected in comparison with the current densities at which the measurements were made.

[725]

V. AN INTERPRETATION OF THE RESULTS.

1. *General Considerations.*

When an attempt is made, from a more general standpoint, to give a connected picture of the laws which hold for the phenomena dealt with, it is necessary in the first place to consider the linear distribution of the potential gradient (mentioned on page 720) along the axis of the discharge within the limits between which the equation $J = a v^2 + B$ holds.

This leads in fact to the important conclusion that the energy used up in a given volume of the discharge tube is *not* added to the kinetic energy corresponding to the stream velocity of the electrical carriers. On the contrary this energy is converted entirely, in the volume in question, into the energy of agitation of the molecules (heating of the walls of the vessel). For it must be remembered that we are dealing with a space occupied by an extremely rarefied gas; if therefore the energy were employed to an appreciable extent in accelerating the carriers of electricity we should expect, in consequence of the great mobility (great free path) of the negative electrons, the potential gradient to diminish considerably towards the anode, while at first with bigger gas density it increases in this direction rather than otherwise and then becomes precisely linearly distributed along the axis. The question then arises: "Why should great quantities of energy be used up in producing irregular motion of agitation in maintaining a current in an extremely high vacuum in which the mean free path of the electrons might be expected to far exceed the dimensions of the tube?"

In this connection it is hardly more than a description of the facts when we summarize as follows:—

> *"The mean free path is here incomparably smaller than that which would be given as a function of the gas pressure alone.*[24]

[726]

If now we search for the physical cause of such a decrease of the mean free path, we can get some insight into the essentials of the thing from the common form of the diagrams 1-21. The discharge begins with a small potential gradient, determined no doubt by charges on the glass walls and therefore as a rule badly defined (cf. sentence C. p. 700). Then the square of the potential gradient increases at a very much bigger rate than that of the first power of the current density (cf. page 719). It looks therefore as if the current itself produced impediments in its path, and if we think of those impediments as coming from discrete centres, the number of these centres will, it is clear, increase rapidly with the current density (since the probability of a collision increases with the number of centres deflecting the electrons). This rapid increase will then continue until a certain limit for the ratio of the density of the electrons from the cathode to that of the gas is exceeded (cf. the deduction on p. 731, and also the description of the subject of investigation p. 674). From this point onwards the increase will be slower and, in the interval within which the law $J = \alpha v^2 + B$ holds, constant. That the formation of these impeding centres is connected with the gas density follows from the fact that the greater the gas density the sooner the greatest attainable value of the ratio of the number of centres to the electron density is reached for a given gas density. This is indeed just another way of expressing the experimental result (A) on page 700. Now the simplest hypothesis which suggests itself is that these centres are ions which are formed by the impact of electrons or some similar cause, and which, on account of their large inert mass, scarcely come into consideration so far as the conduction of the current is concerned. It is evident in fact that in an extremely high vacuum the increased attractive force that an ion, as compared with a molecule, exerts on the cathode rays will cause an appreciable increase in the statistical mean value of the number of collisions.

We arrive therefore at the conclusion that the extraordinary reduction of the mean free path of the nega-[727] tive electrons in extreme vacuo is caused by a suitable electrical excitation of the gas in such a way that the large radius of action of an ion (as compared with that of a molecule) on (slow) electrons can make itself felt by the augmentation of the statistical mean value of the number of collisions.

In what follows the laws of the discharge will be considered more closely, partly in the sense which has just been sketched in a general way, and partly by putting them in such a form as to strengthen the interpretation given above.

2. *The Independence of the Cross-Sectional Area of the Tube.*

Let J_1 and J_2 be the currents corresponding to the given potential gradients V_1 and V_2 in two cylindrical tubes with the radii r_1 and r_2 respectively (Fig. 18) the following laws hold

$$(1) \qquad \begin{cases} J_1 = \alpha_1 v_1^2 + B_1 \\ J_2 = \alpha_2 v_2^2 + B_2 \end{cases}$$

and for

$$(2) \qquad \begin{cases} J_1 = J_2 = J \\ V_1 : V_2 = r_2 : r_1 \end{cases}$$

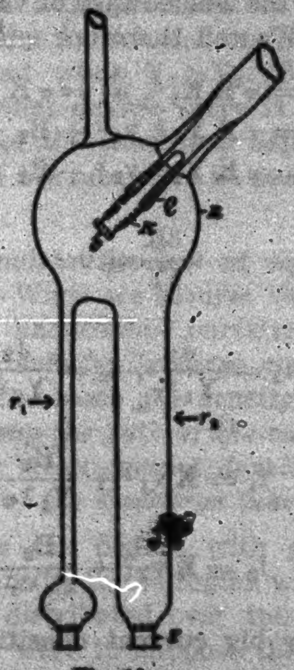

Fig. 18.

Where α_1, α_2; B_1, B_2 are in general functions of the cross-sectional area of the tubes, the nature of the walls of the tube, the gas density or any other peculiarity of the space through which the discharge passes.

If in (1) we put $J_1 = J_2$ and subtract both sides of the equations from one another, we get

$$\alpha_1 v_1^2 - \alpha_2 v_2^2 = B_2 - B_1$$

or

$$\frac{\alpha_1 v_1^2}{\alpha_2 v_2^2} = 1 - \frac{B_1 - B_2}{\alpha_2 v_2^2}$$

If this relation holds as is actually the case for currents for which

[728] $$\frac{B_2 - B_1}{\alpha_2 v_2^2} \text{ is small compared with 1,}$$

we have

$$\alpha_1 : \alpha_2 = v_2^2 : v_1^2 = Y_1^2 : Y_2^2$$

Now since α is independent of the current this relation will hold for the whole range of values for which (1) and (2) hold. We can therefore quite generally write

(5a) $$\alpha_1 = \pi K K_1^2,\ \alpha_2 = \pi K K_2^2$$
$$J_1 = \pi K Y_1^2\ v_1^2 + B_1$$
$$J_2 = \pi K Y_2^2\ v_2^2 + B_2$$

where

(3) $$\frac{\delta K}{\delta Y} = 0$$

Let us now put

(4) $$i_1 = \frac{J_1}{Y_1^2 \pi},\ i_2 = \frac{J_2}{Y_2^2 \pi}$$

and we get

(5) $$i_1 = K v_1^2 + \frac{B_1}{Y_1^2 \pi}$$
$$i_2 = K v_2^2 + \frac{B_2}{Y_2^2 \pi}$$

Consequently for big current densities, where $\frac{B}{Y^2 \pi}$ is small compared with i we have the general result

(6) $$i = K v^2$$

independent of the cross-sectional area of the discharge.

For current densities where $\frac{B}{Y^2 \pi}$ cannot be neglected by comparison with i the relation between current density and potential gradient will be independent of the dimensions of the tube if

$$\frac{B_1}{Y_1^2 \pi} = \frac{B_2}{Y_2^2 \pi} = B$$

that is to say, when

$$B_1 = Y_1^2 \pi B, \ B_2 = Y_2^2 \pi B$$

In this case we should have the general result

$$i = K v^2 + B \tag{6a}$$

It was not until this investigation reached the [729] stage immediately preceding this publication that the values of B acquired a definite meaning, in consequence of the connections developed on pp. 730-731, for the explanation of the processes. From the material previously collected only one definite conclusion can be drawn, namely that when $Y_1 > Y_2$, $B_1 > B_2$ (p. 724). Whether and in what degree there is a constituent of the form $Y_2 \pi B$ for the functional dependence of B on the cross-section of the tube must be reserved for further investigation.

We may formulate the law of equation (6) once more as follows:—When we assume the validity of the laws (1) and (2) and confine ourselves to currents J_1 and J_2 which are sufficiently large compared with B_1 and B_2 then, for the same gas density *the distribution of the potential along the path of the current is uniquely determined by the mean current density, independently of the dimensions of the discharge tube.*

From this we can deduce with great probability that the current density, in the region where (6) is valid, is homogeneously distributed over the whole cross-section. Since if we were to suppose the current density to be greatest in the axis of the tube, as is frequently the case with discharges through gases, it would only be possible to establish equation (6) by the very questionable assumption that the distribution of the current density is rigorously similar in tubes of different diameters while from the nature of the case suggests a considerably more homogeneous distribution with small cross-sections than with great.

When we compare the law (6) with those which have been found, for example, for the positive column in gas pressures such as those in Geissler tubes, we find that its simplicity is not the only astonishing thing about

it. Its independence of the cross-section of the discharge must appear remarkable when we remember the current views according to which the mean free path of the molecules as well as that of the electrons must many times exceed the dimensions of the vessel. We can therefore consistently regard equation (6) as furnishing strong confirmation of the assumption that in the case of the discharge phenomena which have been dealt with, the mean free paths must be considered as vanish-
[730] ingly small by comparison with the dimensions of the vessel, that in fact we must speak of an extraordinary augmentation of the radius of action of the centres distributed through the empty space.

We see further that any pair of the three equations (1), (2) and (6) is sufficient and necessary to determine the third. This is interesting from a physical point of view, when we also take into consideration the fact that, from a certain limiting value of the degree of evacuation onwards, with decreasing gas density but with a constant current, or, as we may now say, with a constant current density the potential gradient remains unchanged. This gives in consequence of equation (6), if we denote the value of k thus defined by K

$$(7) \qquad \begin{cases} i = Kv^2 \\ \dfrac{\delta K}{\delta N} = 0 \end{cases}$$

where N denotes the gas density. We have further from equation (8)

$$(8) \qquad \frac{\delta K}{\delta r} = 0$$

Therefore K is possibly in consequence of what has been said when the function k was introduced, only a function, in the first place, of the chemical nature of the molecules of the gas used to fill the vessel and in the second place of any remaining features of the space through which the discharge passes. In what follows both these variables will be discussed, so far as the existing material permits. Before proceeding to this we shall attach a physical meaning to the connections mentioned at the beginning of this paragraph. The independence of K from the gas density enables us, as will appear from further considerations, to conclude that K is, first and foremost, a factor which depends on the electron density necessary to break off positive charges from the molecules, and it is due to its independence of N that the negative space charge cannot be increased beyond a certain maximum value. From its very nature therefore we should expect K to be independent of the boundary of the discharge space. From this point of view it would have been very perplexing if it [731] had turned out that the coefficient K in the equation $i = K v^2$ was determined, to any extent by the cross-section of the tube, that is to say, in other words, if the characteristic of the discharge were independent of the pressure and yet a function of the (obviously much less essential) dimensions of the discharge tube.

In this sense the fact of the existence of a limiting value of K, independent of N, may be associated with the fact, which forms the foundation of equations (1), (2) and (6), that the characteristic of the discharge is given by the current density and not by the strength of the current combined with a complicated dependence on the shape of the discharge tube. And vice versa if one were to deduce in this way from equation (7) that the current density is the only thing that determines the characteristic, that is to say, that equation (6), or equation (6a) also, is valid, then we should be able by using one of the equations (1) or (2) to deduce the other.

8. *Deduction of the law of the characteristic.*

The law

$$J = a v^2 + B$$ 28)

can be deduced, with the aid of certain assumptions, from the usual notions concerning the conduction of electricity in gases and, more especially, the causal connection between the volume density of the electrical carriers, the potential gradient and the strength of the current. The volume density N — of the negative electrons emitted from the oxide cathode must be regarded as the primary factor. The density N + of the positive charges, which we may ascribe to processes similar to ionization, is assumed—and this is the essential point—to be proportional to N — throughout the range of validity of the law $J = \alpha v^2 + B$

[732] $$\frac{N-}{N+} = a \quad (a > 1)$$

Where a other things being constant, is a function of the gas density N. It is easily seen, if we assume, as is usual, that the positive charges originate from matter, that a will diminish with increasing gas density, therefore

$$\frac{\delta a}{\delta N} \overline{<} 0$$

a result which is confirmed by the augmentation of the potential gradient with diminishing gas density.

It is further assumed that N — (and also N +) is proportional to the number of carriers—for which a special symbol is unnecessary—actually engaged in the conduction of the current; so that therefore all these other quantities are connected with N_- in a linear way.

Let J be the total current when a steady state has set in. A change d J of the current will be, according to what has been stated above, associated with a change dn_- of the density N_-. Consequent N_+ changes by an amount $dn_+ = \frac{1}{a} dn_-$.

Then it is likely, and is rendered more probably by the validity of equation (6), that the distribution of the charges which determine the special distribution of the potential remain geometrically similar to themselves during such a change, that in fact the change in the potential gradient can be taken as proportional to the change in the space charge

(9) $$dv = p\,(dn_- - dn_+)$$

$$= p\left(dn_- - \frac{1}{a}\,dn_-\right)$$

$$= p\,\frac{a-1}{a}\,dn_-$$

Now the change d J of the current depends not only on the number of the carriers of electricity but also on their velocity. Here too there is proportionality. As, however, the velocity is on the other hand proportional to the potential gradient we shall have, with the assumptions that have been made

(10) $$dJ = b\,v\,dn_-$$

Where (b) is a factor which depends mainly on the mobility of the electrical carriers. If we substitute for dn_- the value given by (9)

$$dn_- = \frac{1}{p}\,\frac{a}{a-1}\,dv$$

we get

(11) $$dJ = \frac{1}{p}\,\frac{ab}{(a-1)}\,v\,dv$$

If we put

(12) $$\frac{1}{p}\,\frac{ab}{(a-1)} = 2\,\alpha$$

[733] and integrate (11) we get

(1) $$J = \alpha\,v^2 + B$$

Where B is a constant of integration.

From the above deduction with the help of the equations

(7) $$K = \frac{\alpha}{v\,Y^2}\,\frac{\delta K}{\delta N} = 0$$

we get certain information concerning the functions a and b.

From (12) we have

$$K = \frac{1}{2\,r^2\,p\,v}\,\frac{ab}{a-1}$$

When we remember now that r and p are by their nature independent of N, we see that $\frac{\delta K}{\delta N}$ means essentially

$$\frac{\delta\left(\frac{ab}{a-1}\right)}{\delta N}=0$$

When we carry out the differentiation we get

(14) $$\left(1-\frac{1}{a}\right)\frac{\delta b}{\delta N}-\frac{b}{a^2}\frac{\delta a}{\delta N}=0$$

as $a > 1$ we have also

$$1-\frac{1}{a}>0$$

Since in the region of validity of K the potential gradient does not change as N is varied, therefore

$$\frac{\delta v}{\delta N}=0$$

and consequently also

$$\frac{\delta\left(\frac{\delta v}{\delta n}\right)}{\delta N}=0$$

This becomes, when we remember that p is independent of N and make use of equation (9)

$$\frac{\delta\left(\frac{a-1}{a}\right)}{\delta N}=0$$

therefore

[784]

(15) $$\frac{\delta a}{\delta N}=0$$

and by (14)

(16) $$\frac{\delta b}{\delta N}=0$$

Equation (15) expresses the independence of

$$\frac{N_-}{N_+}=a$$

of N, that is to say: *from a certain maximum value of the gas density downwards the number of positive charges formed per negative charge, i.e., per negative electron is independent of the gas density.*

Since we usually regard positive charges as originating from molecules (or atoms) we can put this result in the following form: *the number of positive charges per molecule increases continually with diminishing gas density in the region of validity of the function K which is independent of the gas density provided other conditions (the potential gradient) are kept constant.*

Always regarding the negative electrons as the primary factor, we must think of the formation of the positive charges as the result of the effects which are conditioned by the electron density and the number and energy of their collisions; and consequently we must conclude that the intensity of these effects, i.e., the amount of energy communicated to a molecule or ion cannot exceed a definite limiting value without the production of a positive charge. Whether these charges are to be regarded as uniting with the molecules to form complex ions, or whether we are to ascribe to them an independent existence in space may be left for the present an open question.

The manner in which we have to regard the formation of positive charges by the action of the electrons on matter, in the case where we have a small gas density on the one hand and a large electron density on the other,[26] does not seem to me to be determined by the kinetic energy of the *individual* electrons, as would be the case according to the usual views of ionization. We must consider rather the space density, the *frequency* and collisions of the electrons in case these collisions are sufficiently frequent to communicate their energy additively to the molecule during the split-
[735] ting off of the positive charges. Obviously it is necessary for this purpose that the frequency of the collisions should be commensurable or of a higher order

of magnitude than the frequency of vibration of the positive charge attached to the molecule and which is to be split off. A related phenomenon has been observed by Kunz (Phil. Mag. 14, p. 614) in the case of the excitation of fluorescence by canal rays. Kunz found that the limiting value of the velocity necessary for the excitation of the fluorescence is smaller when the beam of canal rays is richer in ions.

We can, on the other hand, adopt the view that since the number of positive charges produced (other things being equal) is independent of the number of molecules, there is no causal connection (from the above-mentioned maximum gas density downwards) between the positive charges and matter. This means that these positive charges arise and continue to exist in empty space (in the ether) outside the molecules.

If it were technically possible (cf. p. 713) to vary the chemical nature of the traces of gas in the high grade vacuum in a definite way, we should be able to decide experimentally between these two assumptions. It would then appear whether the quantity K which is independent of the gas density, is a function of a general character or is dependent on the chemical nature of the gas.

A few conclusions can also be drawn from equation

$$(16) \qquad \frac{\delta b}{\delta N} = 0$$

As b was characterised as essentially dependent on the mobility of the charged particles this equation means that the mobility of the electrical carriers is independent of the gas density. The assumption suggests itself that the mean free path of the negative electrons remains unchanged, as the diminution in the number of molecules is compensated by the increase in the radius of action of the remaining ones.

If we were to regard the above conclusion as plausible when extended to positive charges we should be led to a contradiction so soon as we were to suppose these [736] charges to be associated with matter. For the mobility of a multiple-valued ion is greater than that of a single valued one of like mass. We should then have to resort to the possibility that the multiple-valued ions in consequence of their great inert mass or very small free path do not play an appreciable rôle in the conduction of the electricity.

Evidently we could also introduce other hypotheses here. *The problem would be solved in the simplest way if we could establish the existence of free positive charges with a constant ratio of charge to mass, and independent of matter.*

Finally we may point out that the law (p. 719) according to which the potential gradient, for small values of the current density, varies as $J^{2/3}$, can be deduced with similar assumptions and its independence of the pressure similarly interpreted as in the case of

$$J = \alpha v^3 + B.$$

Although such a deduction would support some of the views developed above and more especially the hypothesis of the production of positive charges in space which are independent of matter, it will be left over for the present. For we have seen already that in the discussion of equations (15) and (16) the experimental material at our disposal begins to fail. It is clear that this material can be supplemented in several directions.

Firstly, it is hoped to clear up many points by an improvement in the vacuum by replacing liquid air by liquid hydrogen in the experiments.

Secondly, it would be of interest, as already mentioned, to work out methods for the introduction of chemically well defined gases into high grade vacuum and the investigation of the behaviour of the latter.

Thirdly, the question whether the mean free path of electrons of *known* velocity in the luminous column [787] admits of measurement can be dealt with, as this would give us some idea of the gas density which at present cannot be estimated.

Finally, the question, which was again brought to the front by the last results, as to the nature of the positive charges must be dealt with, especially as some of the earlier experiments in this direction, while not having the force of proofs, have nevertheless not been refuted and still await explanation.

VI. SUMMARY.

1. *Experimental Results.*

(A) Provided that the current density is sufficiently great it is still justifiable to speak of a part of the discharge sufficiently far from the electrodes which at much higher pressures is ordinarily called the positive column (cf. p. 721).

(B) In the region of the investigation for current densities exceeding a certain minimum value the following relation holds:—

$$i = K v^2 \tag{6}$$

Where K is a factor independent of the form of the tube [pp. 727 to 731, especially p. 728, equation (3)].

The connection between current intensity and potential gradient is independent of the shape of the discharge in the sense which is more fully dealt with in the text (p. 729).

(C) From a certain maximum value of the gas density downwards the characteristic of the discharge is entirely independent of the gas density (p. 713), and therefore we have more especially for the factor mentioned under B

$$\frac{\delta K}{\delta N} = 0 \text{ (p. 730).} \tag{7}$$

(D) If the gas density is sufficiently small, we find for current densities between 0 and the regions of B and C the law that the potential gradient varies as J ⅔ (p. 719).

2. *General Conclusions.*

(E) The laws mentioned under B and C can be [788] deduced and interpreted from a more general point of view in which the phenomena of the discharge are associated with the production of positive charges by the negative electrons (pp. 781-783). The conclusions reached in this way led to the consideration of the existence of positive charges which are independent of matter (pp. 783-786).

(F) From the facts summarized under A we have concluded that in the region of investigation the mean free path of the electrons is much smaller than that observed with the same gas density outside the electrical discharge in the positive column.

The materials and apparatus for these investigations were provided to a large extent by a fund connected with the Haertel foundation which was most obligingly placed at my disposal for this purpose by the *Royal Society of Sciences in Leipzig.*

The experiments described were carried out in the Physical Institute of the University of Leipzig. I wish once more to express my heartiest thanks to Geheimrat Prof. Dr. O. Wiener for his support in a work which has required such large resources. I also wish to thank Prof. Dr. Th. Des Coudres for the interest he has taken in the investigations.

THE CONDUCTION OF ELECTRICITY IN EXTREME VACUUM

By J. E. LILIENFELD

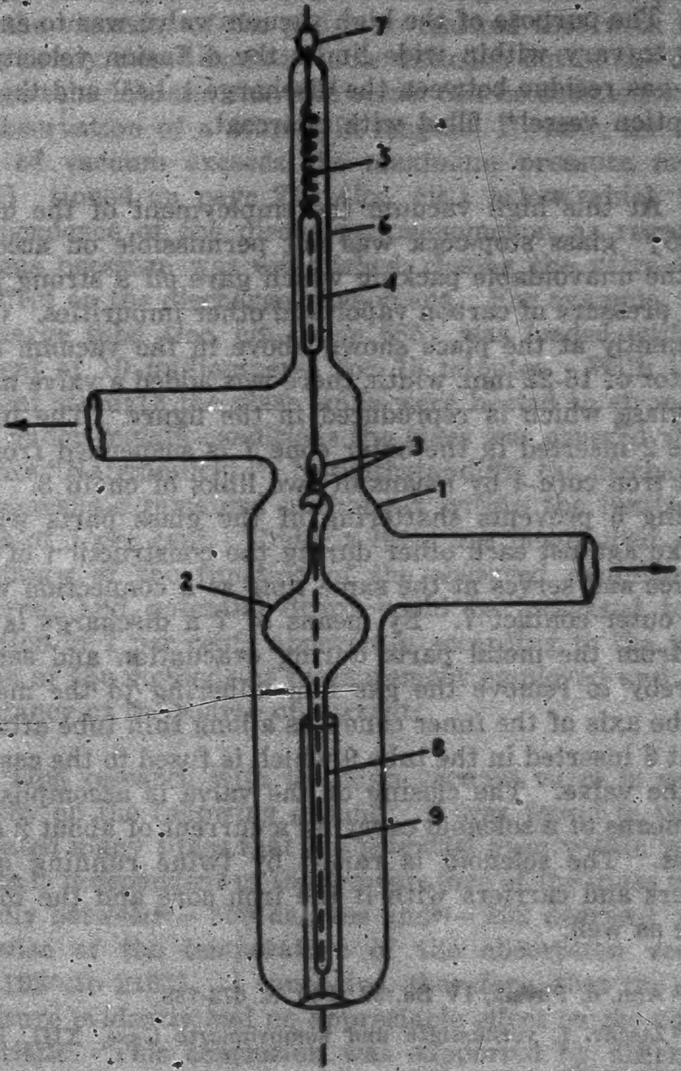
[534]

I.

In my last publication[1] on this subject, a series of general formulæ were collected. In the first place among others there was given the function

$$J = \alpha v^2 + B$$

expressing the relation between the current strength J and the potential drop v at very low pressures obtained by the application of liquid air. It was found, furthermore, that from a definite pressure downward in the region then accessible are independent of the gas density. On the basis of some consequent considerations directions were given on page 736 to 737 for the further investigation of the region dealt with. The present communication concerns itself with the above mentioned improvement of the vacuum which was made possible by the apparatus of the physical institute for the liquification of large quantities of hydrogen[2] which I installed in the mean time, as well as by the employment of the novel high vacuum valve described in the following.



II.

The purpose of the high vacuum valve was to enable one to vary within wide limits the diffusion velocity of the gas residue between the discharge tube[3] and the absorption vessel[4] filled with charcoal.

At this high vacuum the employment of the usual [535] glass stop-cock was not permissible on account of the unavoidable packing which gave off a strong partial pressure of carbon vapor and other impurities. Consequently at the place shown above in the vacuum conductor of 16-22 mm. width, there was added a valve made of glass which is reproduced in the figure. The inner cone 2 inserted in the outer cone 1 is suspended from a soft iron core 4 by means of two links of chain 3. The spring 5 prevents shattering of the glass parts which strike against each other during the construction of the device and serves at the same time as a connection with the outer contact 7. By means of 7 a discharge is set up from the metal parts during evacuation and serves thereby to remove the gas film adhering to the metal. In the axis of the inner cone 2 is a long thin tube attachment 8 inserted in the tube 9 which is fused to the casing of the valve. The closing of the valve is accomplished by means of a solenoid carrying a current of about 2 amperes. The solenoid is raised by twine running over rollers and carriers with it the iron core and the inner cone as well.

[3] Ann. [illegible] Phys., loc. cit., S. 685.

[4] S. 6[illegible]

Obviously the valve does not provide an absolute barrier to the gas. However, at the high vacua in question the viscosity of the gas is so marked that with the valve firmly closed no noticeable diffusion out of the discharge tube into the charcoal vessel can be detected with an observation of a minute in length. If, now, the degree of vacuum exceeds the maximum pressure men- [536] tioned on page 718 (loc. cit.) below which the independence of the discharge phenomenon as regards the gas pressure was established, closing the valve has no effect on the discharge phenomena. For example, the discharge tube (loc. cit., page 685) was loaded with a current of 10 milliamperes for 15 minutes. With this current strength the glass walls were heated so strongly that under certain conditions the glass was covered with intense "Natriumlicht." Notwithstanding, the discharge characteristic remained unchanged within the limits of error of 1 per cent. Under a little less heavy load, the constancy of the function of the observed magnitudes (current and potential drop) could be increased to a fraction of 1 per cent; apparently according to the precision of the methods of measurement employed and the constancy of the source of current.

This research with the high vacuum valve is noteworthy on the following ground. It was found in work repeated many times that the potential drop within wide limits is independent of the temperature of the glass wall (easily between + 300 degrees and — 192 degrees) and likewise of the temperature of the absorption vessel (— 183° to 215°). I concluded, therefore, that the gas pressure evidently had no appreciable effect on the characteristic. This conclusion was supported by different extensive observations such as its independence of the anode material and of the temperature of the oxide cathode. So the obvious objection that the gas pressure had remained constant in spite of all these changes was robbed of its force since it depended substantially only on the diffusion velocity of the traces of gas evolved from the glowing cathode and by the discharge. By the employment of the high vacuum valve which practically stops the diffusion to the charcoal vessel without otherwise changing the discharge, the non-existence of each of the possibilities considered above was proved beyond all doubt.

III.

The improvement of the discharge characteristic was further effected by the application of a bath of liquid hydrogen about the charcoal vessel and also hydrogen solidified in vacuum (— 259°). The experimental means which served for this purpose and in particular the Kryostat, are described on page 688 (loc. cit.). The results [537] may be summarized in the statement that in this markedly extended range, the discharge phenomena were proved independent of the gas pressure by observations lasting hours and repeated in the course of many weeks, which will be given again in a publication planned for the future. The temperature of the charcoal during these experiments varied between — 182° and — 259°; the temperature of the discharge easily between + 300° and — 192°, and the diffusion velocity from the discharge tube to the charcoal vessel varied between approximately 0 and that which took place in a tube of 25-30 cm. in length and cross-section of 18 mm. Furthermore, the temperature of the oxide cathode could be varied between red glow and bright white glow.

It is of interest to add that although the above parts of the discharge tube were often replaced, the same piece of tube with the same exploring wires was used for the exploring wire measurements for several years. The limiting function of the potential drop between these exploring wires and the accompanying discharge characteristic always remained the same with great exactness.

IV.

In the course of the present investigations a light was thrown on the independence of the experimental results as regards gas pressure over such an extremely wide range. For the interpretation of the foregoing results, the following may be remarked.

Along the axis of the discharge tube a linear distribution of potential was experimentally found (loc. cit., page 720).

From the general appearance of the discharge it was concluded that the current was homogeneously distributed in planes *perpendicular to the axis* (page 721). Further it was shown on page 729 that independently of the form of discharge tube, a definite current I was always related to the definite potential drop v. If one designates in general the current strength by J, the cross-section of the discharge path q, and if in two different discharge paths whose cross-sections are q_1 and q_2 at the constant potential drop v, the currents are J_1 and J_2, then

$$J_1 = a\, q_1\, v$$
$$J_2 = a\, q_2\, v$$

[538] in which a is a constant. It therefore follows

$$\frac{J_1 - J_2}{q_1 - q_2} = \frac{J}{q}$$

or if we write $J_1 - J_2 = \Delta J$ and $q_1 - q_2 = \Delta q$ then

$$\frac{\Delta J}{\Delta q} = \frac{J}{q}$$

It follows, therefore, in case at the constant potential drop the discharge cross-section is gradually increased, in every new cross-section element the same current flows, that is to say, the current density i is uniformly distributed over the whole cross-section.

In the light of the unique relation between the potential drop and the current density which is independent of the form of the tube, the potential drop cannot be otherwise than uniformly distributed in cross sections normal to the direction of the current. Therefore, the two vectors, the potential drop and the current density, have everywhere constant values and their direction parallel to the axis of the tube. It follows, therefore, as regards the potential function δ

$$\Delta^2 \delta = 0$$

An expression showing that *in the discharge path there is present no volume density of electricity.*

However, it was shown on page 723 (loc. cit.) that in the discharge path there exists an irregular motion of negative electricity which represents an enormous amount of energy in comparison with the regular motion of current conduction and that consequently, the mean free path of the electrons is very small. Therefore, there is a large volume of density of negative electrical carriers present. On the other hand, we are forced to conclude from the above formulæ that a positive volume density exists which is equal to this negative density, the lines of force originating on the negative charges ending on the positive charges; furthermore, these positive charges must stand in causal relation with the unusual diminution of the free path of the negative electrons.

One would perhaps be inclined in view of the fact that the energy necessary for the production of the positive charges is independent of the gas pressure within such wide limits, to conceive of the charges themselves as existing independently of the material.
[539]

On the other hand, one must remember that there are possible explanations which are contradictory to the foregoing. For example, an unlimited independence of the characteristic as regards gas pressure with decreasing gas pressure could be simulated by the following arrangement. From a certain maximum number of molecules m_1 per unit volume to a number of m_2 m_1 the characteristic might be independent of m. For still smaller gas pressures, however, a law might hold that as long as m is less than m_2, a partial gas pressure, independent of the temperature of the electrodes and walls of the vessel, is produced in addition by the discharge until again the limiting function for the relation of the current to the potential drop comes into force. As regards the way and manner in which this compensating partial pressure originates, and likewise as regards the origin of the molecules, nothing further can be said. In any case, it is enlightening that the foregoing observations were exactly as though from a density m_2 downward the unlimited independence of the gas pressure held.

The region dealt with here is, however, capable of a so many sided further investigations that it appears at present to be too early to formulate any definite opinions concerning the facts which are based on the collected experience.

[TRANSLATION]

ON A METHOD OF PRODUCING VERY SOFT ROENTGEN RAYS IN THE HIGHEST VACUUM

By H. DEMBER

(Entered July 19, 1911)

[601]

1. According to the quantum theory, a certain minimum amount of energy is necessary for the production of a Roentgen impulse. In the following a method is described which makes it seem possible to measure such amount of energy directly. At the same time this arrangement makes possible the production of X-rays over a great range of hardness.

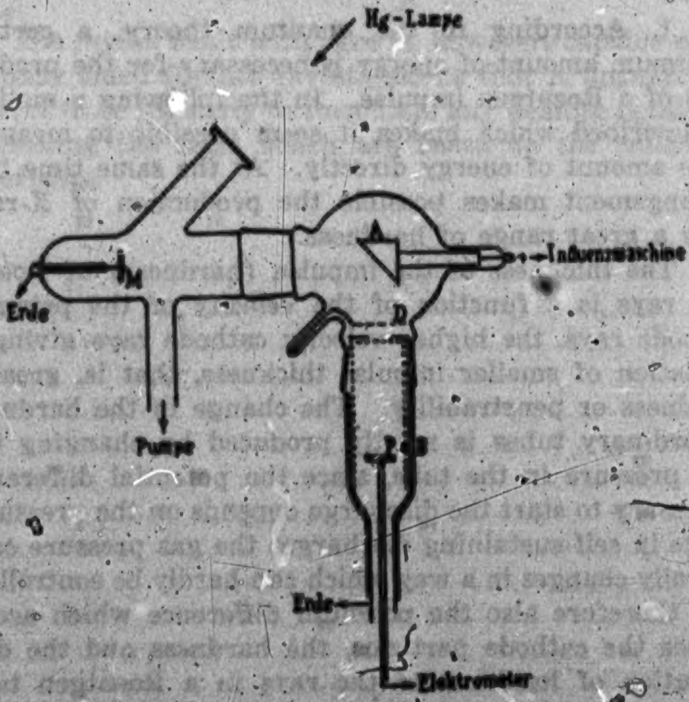
The thickness of the impulse (hardness) of Roentgen rays is a function of the velocity of the primary cathode rays, the higher velocity cathode rays giving a radiation of smaller impulse thickness, that is, greater hardness or penetrability. The change in the hardness in ordinary tubes is mostly produced by changing the gas pressure in the tube, since the potential difference necessary to start the discharge depends on the pressure. Since in self-sustaining discharges the gas pressure continually changes in a way which can hardly be controlled, and therefore also the potential difference which accelerates the cathode particles, the hardness and the distribution of hardness of the rays in a Roentgen tube is very variable.

Experiments with the Roentgen rays of constant or single thickness of pulse or with a range of constant distribution of hardness are therefore exceedingly difficult and can only be made in an unsatisfactory way by using selectively absorbing filters.

The photo-electric action gives a means whereby cathode rays can also be produced in the utmost vacuum, and therefore an attempt was made to increase the velocity of the photo-electric electrons to such an extent [602] that they can produce Roentgen rays when they bombard the anti-cathode. The proof of the existence of the harder rays was done with a photographic plate; the very weak rays could be tested for by the action of Roentgen rays to emit electrons from matter and the consequent generation of positive electricity.

2. *Experimental Arrangement.*

The photo-electrically sensitive magnalium or copper plate M (see figure) was submitted to the light from



a quartz mercury vapor lamp, the light passing through a quartz plate which was cemented to the tube. In order to accelerate the liberated electrons a potential difference was applied between the cathode M and the anti-cathode A which was coated with platinum foil. The Roentgen rays produced by the bombardment of the photo-electric electrons passed through a wire net of 1.8 sq. mm. mesh, and thus reached the adjoining tube B. In this adjoining tube a suitable aluminum box was placed which con- [603] tained the photographic plate. As a source of potential a 20-plate Toepler influence machine was used. The voltage applied to A could be varied between 100 and 10,000 volts and kept constant for hours with the help of a Gray point shunt and a variable liquid resistance. The fluctuations in potential were so small that they could hardly be noticed on the Braun electrometer which was used to measure the potentials.

3. Since there was a possibility of cathode rays reflected from the anti-cathode getting into the adjoining tube, there was placed in order to prevent this a grounded net D opposite the positive anti-cathode, so that the electrons entered a retarding field. For the evacuation was used first a Gaede pump and then charcoal which was dipped into liquid air.[1)] In the final experiments the pressure was less than 10^{-5} mm. Hg.

4. *Experiments.*

With the help of the photographic plate which was wrapped with the light-tight black paper used in packing the plates, a picture of a lead strip .2 mm. thick and 1 to 2 mm. wide which was attached to the plate could be obtained with a difference of potential of 6000 volts, and an exposure of two hours, and so also with 4000 volts. On the other hand, with 2000 volts no impression was obtained on the photographic plate after an exposure of several hours. This same result was obtained with magnalium as well as copper as cathode. Also, when the photographic plate was covered with two light-tight aluminum foils of 0.00035 cm. thick instead of the black paper, no definite blackening was produced with an exposure of two hours. Only when the very thinnest aluminum foils were used, such as is used for making [604] the most sensitive leaf electrometers, a potential difference of 2000 volts showed a uniform blackening of the plate besides the blackening due to the action of the ultra-violet light through the pores of the aluminum foil.

5. The latter experiment gave the suggestion to further follow by means of another method these soft Roentgen rays, and to determine the lower limit of the potential difference necessary to accelerate the primary cathode rays.

For this purpose use was made of a phenomenon discovered by P. Curie and G. Segnac[2] and quantitatively investigated by E. Dorn,[3] that Roentgen rays emit negative secondary rays. When Roentgen rays fall on a metal plate it becomes charged positively. This is a phenomenon which is in many respects analogous to the photo-electric effect. For example, the velocity of the emitted electrons is found to depend in such a way on the hardness of the Roentgen rays which cause their emission that the electrons of highest velocity give rise to the harder rays.[4]

6. In order to prevent positive ions formed by collision ionization of the residual gas from entering the adjoining tube M and so charge up the plate positively, the wire gauze D was connected to the positive anticathode by means of a sealed-in platinum electrode. The metal plate from which the Roentgen rays were to emit electrons consisted of a polished platinum disc P, 2.2 cm. diameter, which was inserted through amber insulation in a brass cylinder blackened with soot. This was lined according to von Baeyer with a wire net blackened with soot (see figure). Both the brass cylinder and wire net were blackened with soot. Furthermore, at the opening to the cylinder was placed a lead diaphragm with 1.5 cm. opening. The distance of the platinum plate P [605] from this diaphragm was 5.6 cm. It was chosen so large to prevent electron reflection inside the cylinder.[5]

To measure the positive excitation, a Lutz string electrometer was used which was very suitable for this purpose on account of its low capacity (4.4 cm.). The electrometer was used with string connection and its sensitivity was so chosen with the help of the string voltage and that of the auxiliary battery that 1/10 volt could be read with certainty. All connections to the electrometer and grounding key were carefully shielded in the usual way from electrostatic disturbances.

7. The following table gives the potentials acquired by the plate P in relation to the potential difference which accelerated the photo-electric electrons. The cathode used here was a magnalium disc.

Velocity of Photo-Electric Electrons Volts	Velocity of Roentgen-Electric Electrons Volts
9500	3.6
6000	2.0
4000	1.35
1000	1.1
500	0.95
250	0.7

For velocities of the primary rays below 250 volts, Roentgen rays could not be noticed with certainty with this method, since the charge acquired by the plate as the result of the ultra-violet light also increased to 0.7 volt. For measurements above 250 volts the actions of the Roentgen rays and ultra-violet light could be separated by observing the rate of accumulation of charge.

From these experiments it follows that Roentgen impulses can still be produced by electrons of energy of $4.69 \,.\, 10^{-10} \frac{250}{300}$ erg. $= 3.9 \,.\, 10^{-10}$ erg. Furthermore, [606] these results also show that excitation, i.e., the velocity of the secondary electrons depends on the hardness of the Roentgen rays.

It is not in place on the grounds of the measurements made thus far to compute a quantitative relation between the hardness of the Roentgen rays which were produced by photo-electric electrons and the velocity of the secondary rays, since the small charges acquired by the plate depend on the gas occluded in the excited metal and this was not considered here.

REFLECTION AND SECONDARY RADIATION OF PHOTOELECTRICALLY LIBERATED CATHODE RAYS.

A. GEHRTS.

Extract from Berlin Dissertation.

I. *Proof of a Reflected and Secondary Radiation of Photoelectrically Produced Cathode Rays.*

[995]

1. The secondary radiation produced in gases and solid bodies by photoelectrically liberated cathode rays is investigated in detail by Lenard[1] in a series of works. Lenard used essentially a phosphoroscopic method and obtained the following results:

(a) *For gases:* "If the primary velocity is below 11 volts, no noticeable secondary radiation takes place. From 11 volts up the number of secondarily liberated electrons suddenly increases rapidly, being at first almost proportional to the velocity excess over 11 volts; later this increase must be slower. The secondary radiation reaches a maximum in air at about 300 and in carbonic acid at a primary velocity of about 500 volts. With further increase in primary velocity there is a gradual decrease."

(b) *For solid bodies*, especially platinum, the results were as follows for a primary velocity U "Rapid increase of the effect was shown above U = 100 volts up to about U = 200 volts, this being unnoticeable in the neighborhood of U = 0; the increase up to about U = 400 volts was slow and above that nearly constant up to U = 1000 volts, while above this there was a slow decrease. If it is taken into consideration that from U = 400 to U = 1000 volts, the primary amount coming [996] through the diaphragm increases from 60 to 80 per cent, it follows that the primary velocity of maximum effect is for Pt = 400 volts.

In gases as well as in solid bodies, the secondary radiation was greatly diffused and of very small velocity (platinum = 10.8, copper = 7 volts).

A reflection of the primary rays was not noticeable in Lenard's experiments.

Recently, experiments made by O. v. Baeyer[2] with slow cathode rays, which were liberated from a glowing oxide cathode, have now yielded a reflection of the primary rays for velocities of 10 to 15 volts and under.[3]

A reflection could therefore also be assumed for small radiation velocities of photoelectrically emitted cathode rays. The following experiments serve to prove the existence of this and give an improved electrometric investigation of the secondary radiation.

2. *Experimental Arrangement.* The experimental arrangement used which was constructed essentially according to that of Mr. v. Baeyer, is represented in Fig. 1. The light of a quartz-mercury high-pressure

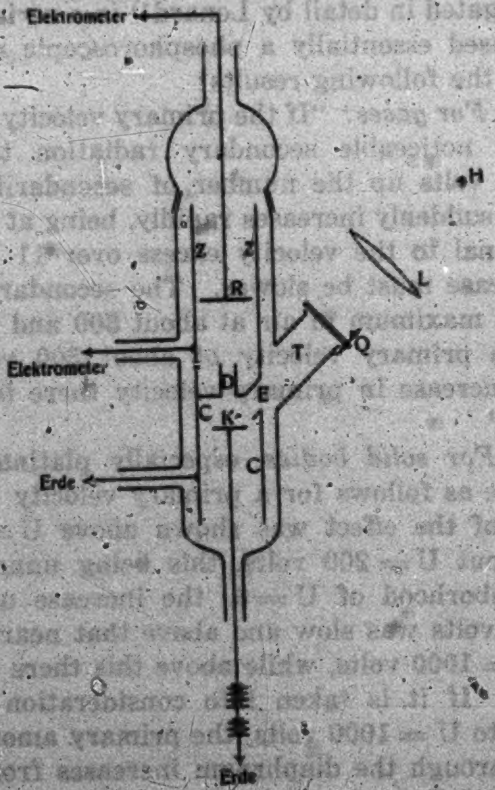

Fig. 1. Versuchsanordnung zum Nachweise der reflektierten bzw. Sekundärstrahlung.

lamp H, furnished by the firm of W. C. Heraeus in Hanau, was concentrated through a quartz lens L of about 10 cm. focal length and fell at an angle of about 45° through a side tube T of an experimental tube 3 cm. wide on the highly polished copper cathode K, 1 cm. in diameter, there causing an electron emission. The side tube T was closed air-tight by a parallel quartz plate G, which was cemented to it and which was 3 mm. thick and cut perpendicular to the optical axis. The copper cathode K was surrounded by a brass cylinder C, open on one side and grounded, 2 cm. in width in which a [997] small brass tube D, having thin walls 1 cm. in length and 5 mm. wide serving as a diaphragm, was centrally inserted. A slanting cylindrical tube E made possible the entrance of light in the cylinder C.

The electrons liberated from the cathode K after passing the diaphragm tube D struck the "reflector," a metallic plate R having a diameter of 1.5 cm., which could be moved parallel to itself in a brass cylinder Z, 2 cm. in diameter and 5 cm. long, by help of a small electromagnet. A large ground joint which was made tight by means of rubber grease, served for changing the reflector R. The reflector R as well as cylinder Z surrounding it were insulated with amber. The cylinders C and Z and the diaphragm D were properly centered and were well covered with wax-candle black.

[998]

Mica diaphragms prevented any part of the metal in the tube with exception of cathode K from being struck by direct ultra-violet light. The mercury lamp was fed by storage battery current (140 volts) and burned generally with terminal voltage of 70 volts which was continually controlled. The electrons produced at the cathode K could be accelerated, which was done by help of a small storage battery whose negative pole was connected to K and whose positive pole was grounded.

The glass apparatus described was evacuated by means of a Gaede pump under steady heating of the coconut charcoal in a side tube up to about 400° C. The charcoal had been previously heated in air nearly up to red heat and then was freed of the tars and gases still clinging to it by energetically heating in the vacuum several phosphorous pentoxide receptacles being connected to it. A three to four hour evacuation was found to be sufficient for obtaining hard Roentgen vacuum. The tube was then disconnected from the Gaede pump and the charcoal cooled in liquid air. In order to obtain perfect constancy in the phenomena, it was cooled at least three hours before measurements were taken. In spite of the cement and ground joints used, a very good vacuum was obtained in this manner.[4)]

The stream of electrons flowing from the reflector R and the cylinder Z surrounding it, was now measured. The current was measured by means of a Dolezalek electrometer having a sensitivity of 2.10^{-4} volts/second, and a Bronson resistance. The resistance was constant for the whole range of voltage involved. A volt effect was always present but was not disturbing in any way when the measurements were made. In order to be free from a possible disturbing influence of temperature variations,[5)] the resistance was inserted in paraffin. All the leads to the electrometer, protected against static [999] disturbances, passed in tubes or cases of sheet zinc.

3. *Measurements and Results.* In order to measure the secondary or reflected radiation, the current was ascertained which flowed from the reflector R and the cylinder Z surrounding it, first (J_1) when the reflector was drawn back into the cylinder so that both formed a Faraday cylinder, and then (J_2) when the reflector shut off the cylinder in front. In the last case the reflected or secondary radiation is caught by the cylinder C. The quotient $\frac{J_1 - J_2}{(J_1)} . 100$ gives the reflected or secondary radiation in percentage of the incident radiation. In these measurements it is assumed that double reflection is never made noticeably disturbing, especially when the reflector stands at the lower end of Z. The peculiar form of the blackened cylinder C standing opposite, as well as the observation (compare Table 5 below) that soot gives an extraordinarily weak secondary cathode radiation, offers sufficient guarantee for this. It may also be remarked that drawing the reflector into the cylinder Z 3 cm. is sufficient to obtain complete reflection or secondary emission which argues for a greatly diffused character of secondary radiation.

The following Tables 1-5 are the result of such measurements; they give the reflected or secondary radiation for various reflectors in relation to the velocity of primary radiation. The primary velocity given in the first columns is everywhere expressed in terms of the potential between cathode X and anode C in which the potential of one accumulator was put equal to 2 volts. Strictly speaking, the primary velocity must everywhere be increased by the amount of the initial velocity of the liberated electrons, which, according to the available measurements on copper, might be estimated on an average at 1 volt. The graphical representation of the [1000] tables is given in Figures 2-6.

4. *Discussion of the Results.* As is to be seen from the tables given, when Table V with soot is disregarded, and even more distinctly from the accompanying curves of Figures 2-6, a sudden variation occurs in the relation of the quotient $\frac{J_1 - J_2}{J_1} \cdot 100$ when the primary velocity is 11 volts. While the quotient diminishes up

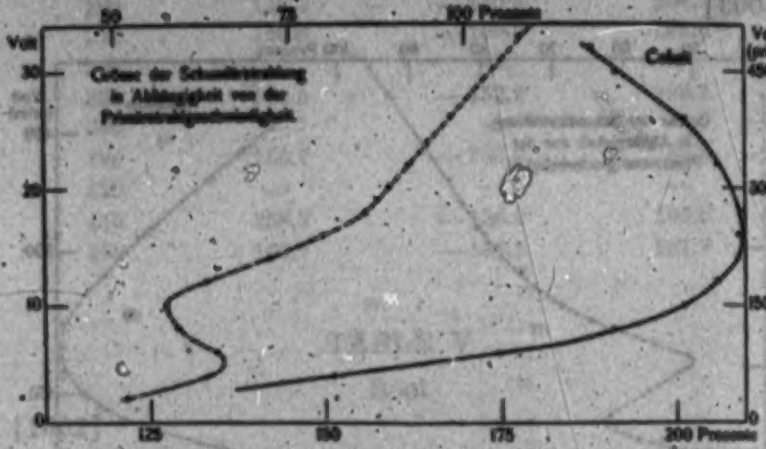

Fig. 4. Tabelle 3.

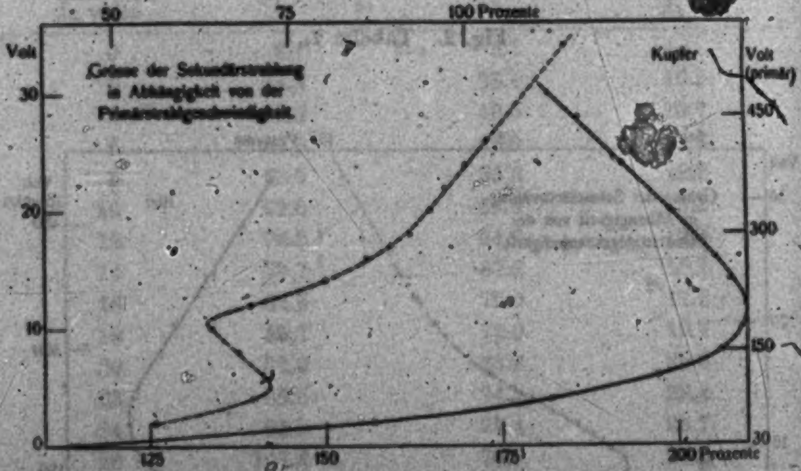

Fig. 5. Tabelle 4.

[1004] to 11 volts with increasing primary velocity, it suddenly increases very rapidly when the velocities are greater than 11 volts. In curves of Figures 2-6 this is expressed in the sharp bend at 11 volts. The phenomenon appearing so suddenly above 11 volts is to be interpreted as the secondary radiation discovered by Lenard. [1005] It increases rapidly with increasing primary velocity and attains the value of primary radiation at about 30 volts—this point varies slightly with the material and the surface condition of the reflector. It was traced up to a primary velocity of 500 volts. Up to 200 volts there was an increase in the secondary radiation, nearly proportional at first (from 20 volts on) to the surplus velocity over 20 volts, and later more slowly,

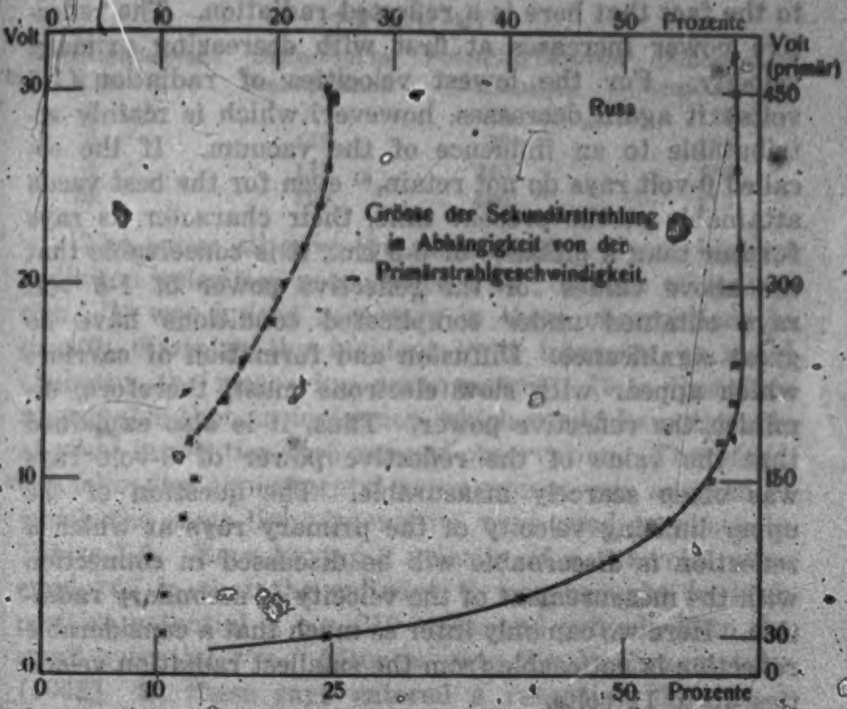

Fig. 6. Tabelle 5.

similar to that substantiated by Lenard for gases. From 220 volts up, the secondary radiation again decreases slowly. This decrease Lenard tries, presumably rightly, to attribute to the fact that a very rapid primary electron remains too short a time in the atoms at the surface of the reflector to cause a sufficient disturbance there. Lenard finds a primary velocity of 300 volts for the optimum of the effect, a result which agrees excellently with that of 220 volts given here considering his [1006] more qualitative phosphoroscopic method. The lower limit for the primary velocity at which a secondary emission is still to be noted is therefore 11 volts. The fact that for gases as well as for metals the same lower limit of 11 volts was ascertained for the velocity of primary radiation is a good support for the assertion of Lenard as to the identity of the secondary radiati[illegible] of solid and gaseous bodies.

Below 11 volts the quotient $(J_1 - J_2) / J_1 . 100$ decreases with increasing primary velocity. This points to the fact that here is a reflected radiation. The reflective power increases at first with decreasing primary velocity. For the lowest velocities of radiation (1-5 volts) it again decreases, however, which is mainly attributable to an influence of the vacuum. If the so-called 0-volt rays do not retain,[6] even for the best vacua attainable at the present time, their character as rays further than a distance of 5-6 cm., it is conceivable that the above values for the reflective power of 1-5 volt rays obtained under complicated conditions have no great significance. Diffusion and formation of carriers which appear with slow electrons must, therefore, diminish the reflective power. Thus, it is also explained that the value of the reflective power of 0-volt rays was often scarcely measurable. The question of the upper limiting velocity of the primary rays at which a reflection is discernable will be discussed in connection with the measurement of the velocity of secondary radiation. Here we can only infer so much that a considerable reflection is noticeable from the smallest radiation velocities up to 11 volts.

Soot behaves peculiarly in regard to the reflective power as well as the secondary radiation (Table V, Fig. 6). It indicates both phenomena only in a small [1007] degree. The turning point at 11 volts shown in the other curves here disappears.

A distinctly marked influence as to material is shown neither in the case of secondary radiation nor of reflection.

5. *Sources of Error.* In the observation recorded, only the secondary radiation in the vapor residuum (collision ionization) and the production of carriers for lower primary velocities were presumably the sources of error. The influence of both was ascertained in special experiments. First saturation current curves were made in connection with the series of observations given above, in that the current flowing away from the cylinder C, Z and the reflector R was ascertained in relation to the potential between K and C. As an example of an observation of this sort, the following series is given which was ascertained immediately after the conclusion of Table I.

TABLE VI

Potential between K and C.	Deflection in scale division	Potential between K and C.	Deflection in scale division
0 volt	74	26 volt	120
2 "	119	32 "	120
4 "	119	240 "	120
10 "	120	480 "	119

The series all gave the same result. Up to highest radiation velocities used, there was no trace of ionization. It was indeed necessary in these observations to greatly diminish the incident light intensity to avoid changing the measuring arrangement. It is therefore conceivable that an ionization which would be noticeable at great intensities here escaped observation. Therefore, the following experimental arrangement was adopted in which the same light intensities were used as above in Tables 1-5. Rays having a velocity of a ± x volts were employed in that the cylinder C was brought to high positive potential *a*, e.g, 210 volts, and cathode K to the small potential ± x. After passing the diaphragm tube [1008] D, these rays entered a retarding field of *a* volts between R and Z on the one side and C on the other. The current flowing from Z and R was measured. The result was as follows:

TABLE VII.

a	± x	Current flow from Z and R in scale divisions.
+ 210 volts	— 4 volts	125
+ 210 "	— 2 "	120
+ 210 "	0 "	64
+ 210 "	+ 2 "	0
+ 210 "	+ 4 "	0
+ 450 "	+ 2 "	0
+ 450 "	+ 4 "	0

In the latter case (a = + 450 volts, x = + 4 volts) all the positive ions produced by impact or otherwise had to be transported to K and Z. Thus the error caused by impact ionization is surely less than 1 per cent and may be disregarded in the above measurements.

In order to study the influence of the formation of carriers which can only be noticeable when the radiation velocities are small, the diffusion of the primary rays was investigated in a manner similar to the investigation of von Baeyer.⁷⁾ This was done by measuring the current flowing away from the reflector R when the plate R was at varying distances from the diaphragm D while the cylinder Z was grounded.⁸⁾ Table VIII gives an example of measurements of this kind which were made for velocities of primary rays of 1, 3, 5 and 11 volts.

TABLE VIII

Distance R-D in mm.	**Current from R at a primary velocity of**			
	1	**3**	**5**	**11 volts**
8	2.1	27.0	26.0	44.5
14	2.1	26.5	26.0	44.0
20	2.0	22.0	25.0	43.0
30	1.3	17.0	21.0	42.0
45	0.5	12.0	15.0	36.0

[1009]

As is to be seen from this, the cone of rays arising from the tangential components, always present when there is photoelectric liberation and arising as a result of the dispersion through the vapor residuum, strikes the cylinder sheath Z for 1 and 3 volt rays about 2 cm. distant from the diaphragm D, and 5 volt rays about 3 cm. distance and for 11 volt rays about 4.5 cm. distant from diaphragm D. From this it follows that the dispersion and carrier formation is of influence when the velocities of the rays are small, from 1-5 volts, but not, however, for 11 volt rays.

Reflected light nowhere fell on the plate R nor the cylinder Z. If the electrons liberated from the cathode K were held back by application of a sufficiently small positive potential, the electrometer never indicated a trace of a deflection.

II. *Velocity Measurement of the Secondary and Reflected Electron Radiation.*

6. The rather sudden start of the secondary radiation when the primary velocity amounts to 11 volts must manifest itself in a variation of the velocity distribution curve of the electrons leaving the reflector. The reflected radiation generally has to indicate the velocity of the primary radiation while, according to the observations of Lenard, a small natural velocity independent of the velocity of the primary rays is to be expected for the secondary radiation.

The velocity of the electrons emitted from the reflector was measured according to the method used by von Baeyer for the same purpose in the case of oxide cathodes. In the space between the diaphragm tube D and the cylinder C, there was introduced a soot-covered ring B insulated with amber and the space was closed by a fine meshed soot-covered wire net (Fig. 7). The reflector R closed off the cylinder Z in front. Otherwise, the arrangement is the same as above (section 2). The [1010] parts C, Z and R were charged to the same positive potential with respect to K so that in the space between R and the wire net the secondary radiation could be developed undisturbed. The current flowing from B was measured. By variation of the field between B and C, the velocity of the electrons bombarding B could be determined. In this manner the data given in Tables 9-12 were procured, which are partially represented in [1011] the curves 8-10.

Geschwindigkeitsverteilungskurven der reflektierten bezw. Sekundärstrahlung für 10-Volt-Strahlen primär.

Fig. 8. Tabelle 9.

7. *Discussion of Results.* As is shown by the
[1013] curves in Fig. 8-10, there is, for example, a distinct difference between the curves for the 11 volt rays and those for the 80 volt rays. In the latter case a ma-
[1014] jority of the electrons (about 75%) have a velocity of between 0 and 4 volts, while in the curves for the 11 volt rays 50% of the electrons show velocities above 4 volts. In case of the 11 volt rays we deal essentially with a reflected radiation; yet, the quickly increas-

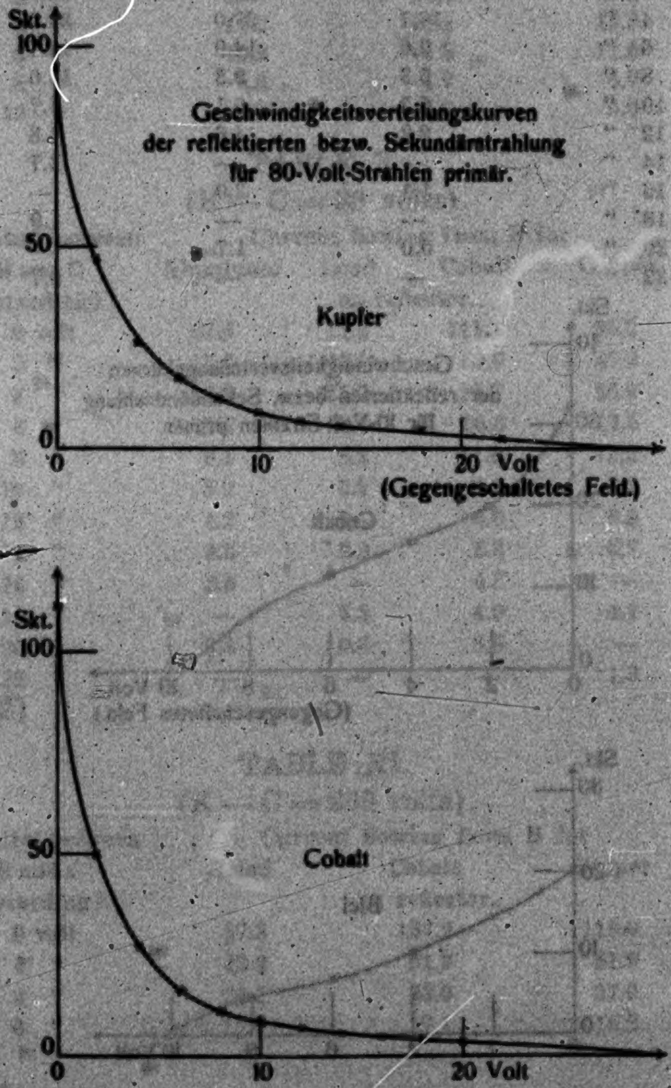

Fig. 9. Tabelle 10.

[1015] ing fall between 0 and 4 volts which was not inconsiderable and which took place with increasing primary velocity, indicated the existence of a secondary [1016] radiation even at 11 volts. A secondary radiation or reflected radiation with a velocity greater than 25 volts was no longer noticeable even for the most rapid primary rays (500 volts).

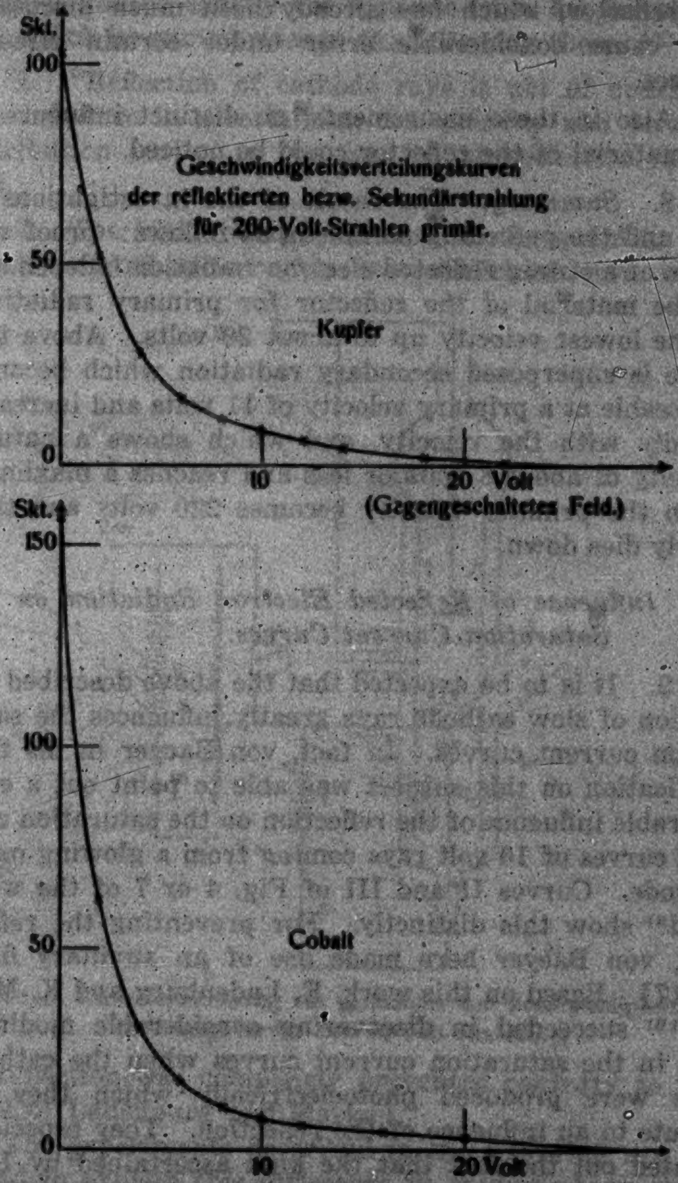

Fig. 10. Tabelle 11.

The measurements, however, may only properly be indicated as qualitative as von Baeyer has already explained. The diffused course of the rays coming from the reflector, which has already been much discussed, may cause considerable error under certain circumstances.

Also in these mearements, no distinct influence of the material of the reflector could be noticed.

8. *Summary.* The result of the investigations of this and the preceding section is as follows: proof was given of a strong reflected electron radiation independent of the material of the reflector for primary radiations of the lowest velocity up to about 20 volts. Above this there is superposed secondary radiation which becomes noticeable at a primary velocity of 11 volts and increases rapidly with the velocity, and which shows a natural velocity of about 8 volts or less and reaches a maximum when the primary velocity becomes 220 volts and then slowly dies down.

III. *Influence of Reflected Electron Radiation on the Saturation Current Curves.*

9. It is to be expected that the above described reflection of slow cathode rays greatly influences the saturation current curves. In fact, von Baeyer in his first publication on this subject was able to point out a considerable influence of the reflection on the saturation current curves of 10 volt rays coming from a glowing oxide cathode. Curves II and III of Fig. 4 or 7 of the work cited[9)] show this distinctly. For preventing the reflection, von Baeyer here made use of an auxiliary field. [1017] Based on this work, E. Ladenburg and K. Markau[10)] succeeded in discovering considerable modification in the saturation current curves when the cathode rays were produced photoelectrically which they attribute to an influence of the reflection. They especially pointed out the fact that the kink ascertained by Lenard[11)] in the quantity and velocity distribution curve vanishes when reflection is prevented; that it is therefore not due to any surface force. They also were able to show that a very definite narrowly limited range of velocity of the liberated electrons corresponds to each exciting wave length. They made use of an auxiliary field for avoiding reflected cathode radiation at one time

and at another time a Faraday cage and in both cases obtained the same result. Recently, however, Klages[12] obtained results exactly the opposite from his investigation which he summarizes in the following theses.[13]

1. "Reflection of cathode rays is not of considerable influence in ascertaining the quantity and velocity distribution curves in the case of photoelectric radiation.

2. The kink found by Lenard in the quantity and velocity distribution curves was confirmed even when

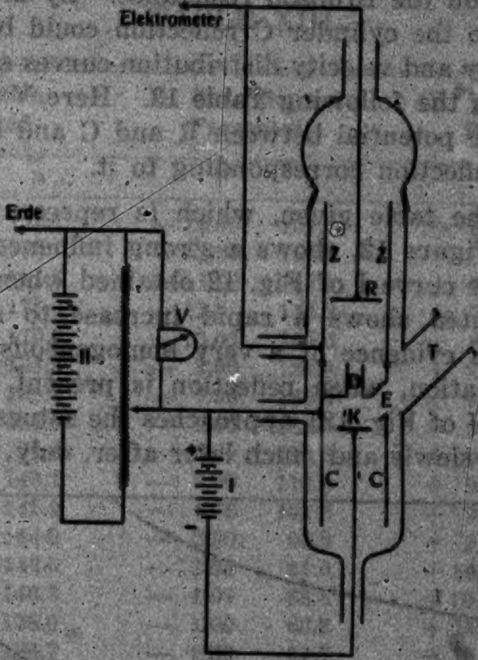

Fig. 11. Versuchsanordnung zur Aufnahme der Geschwindigkeitsverteilungskurven von 10-Volt-Strahlen.

the reflection was completely prevented contrary to the doubt of Ladenburg and Markau."

The experiments described in the following are intended to explain this difference in opinion; they show distinctly an influence of the reflection on the quality and velocity distribution curve, as well as a dependence of the kink on the presence of a reflected radiation.

10. In order to make perfectly clear the influence of the reflected electron radiation on the quantity and [1018] velocity distribution curve of the photoelectri-

cally liberated cathode rays, the experiments of von Baeyer with 10 volt rays were repeated when the cathode radiation was photoelectrically liberated. The experimental arrangement was now as follows (Fig. 11). The experimental tube described in paragraph 2 was used except that this time a constant potential of 10.4 volts was maintained between cylinder C and cathode K which was produced by battery I. Battery I, cylinder C and cathode K were then raised by the battery II whose one pole was grounded to a measurable (by the millivoltmeter V) positive or negative potentials with respect to R and Z which was on the Bronson resistance. By drawing the plate R into the cylinder C reflection could be avoided. The quantity and velocity distribution curves so obtained are given in the following Table 18. Here V stands for [1019] the potential between R and C and *a* the electrometer deflection corresponding to it.

11. The table given, which is represented in the curves of Figure 12, shows a strong influence of reflection. While curve I of Fig. 12 obtained when reflection was prevented shows a rapid increase to saturation, which gives evidence of a very homogeneous character of the radiation, when reflection is present, the curve [1020] (II of Fig. 12) approaches the saturation value much more slowly and much later after, only with accel-

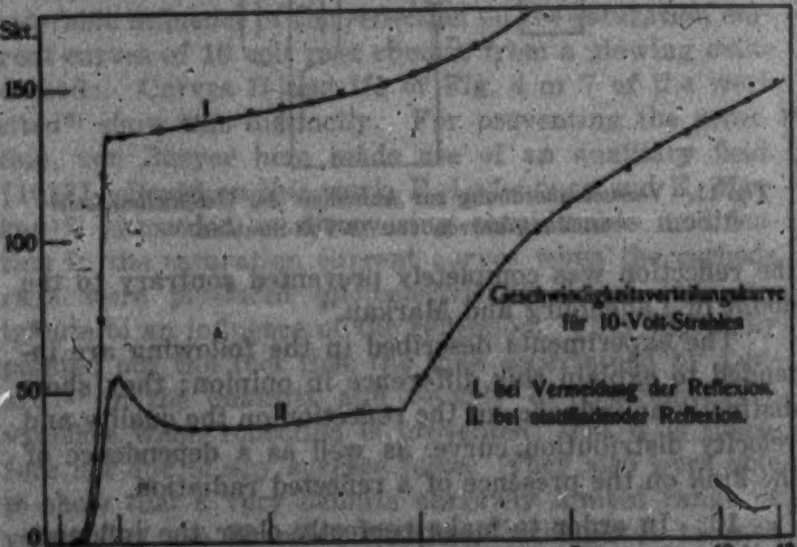

Fig. 12. Tabelle 18.

erating fields. That the saturation is not an ideal saturation in curve I, i.e., that a further slow increase can also be detected beyond 10 volts retarding, might be attributed to the fact that with increasing field between the cylinders C and Z there is a variation in the conditions of emanation of the rays leaving the diaphragm tube. The knob appearing in the curve entitled the "reflection not prevented" at 10 volts retarding is explained by the peculiar behavior of the slowest rays frequently mentioned above, which is based on the vacuum being insufficient for this.

12. After this preliminary experiment we proceed to point out the influence of the reflection on the saturation current curves for the unaccelerated photoelec-

trically liberated cathode rays. The following is the idea underlying the experiments. If the reflection has considerable influence on the curve form, and because the reflected radiation is greatly diffused, the curves [1021] must be freed more and more from the errors resulting from reflection when the distance between plate receiving radiation and intercepting plate is increased, for with increasing distance between the plates a smaller and smaller part of the reflected rays turns back to the illuminated plate and thus lessens the radiation, providing that the surrounding region does not reflect to any noticeable degree. It is especially to be expected that the kink mentioned, in case it is the result of the reflection, is made to disappear by enlargng the distance between the plates.

13. On account of these considerations the following experimental arrangement (Figure 13) was finally chosen after a large number of preliminary experiments. The light of the mercury high pressure lamp after being concentrated by a thin quarts lens falls through the 4 mm. diaphragm in the cap of the brass cylinder C open on one side, 3 cm. wide and 5.5 cm. long normally

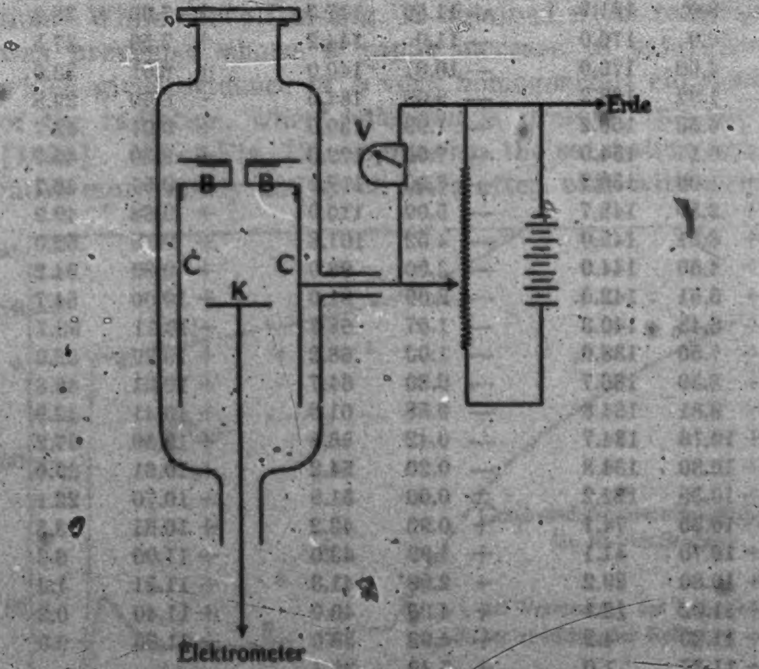

Fig. 13. Versuchsanordnung zur Ermittelung der Mengen- und Geschwindigkeitsverteilungskurven.

[1022] on the illuminated copper plate K having a diameter of 1.5 cm. The cylinder C is closed on one side by a brass cap B polished highly within and inserted in a small additional tube which carried a mica diaphragm protecting the cylinder from direct light. All the parts—with the exception of the highly polished cap—are well covered with wax-candle black. The radiating plate K is moved by an electromagnet in a direction parallel to itself. It was well insulated with amber and lay on the measuring device described above. The cylinder C was brought to the desired potential by branching from the circuit of some storage cells. In the following, the potentials are always calculated as positive when they retard the electrons emitted from K.

The following results which are recorded in Tables 14 and 15 were obtained with this arrangement. In these tables V stands for the potential maintained between K and C or B and a the corresponding electrometer deflection.

14. An influence of the distance between the plates is recognizable from the data submitted and even more distinctly from the curves of Figures 14 and 15. While the kink is distinctly present when the distance K — B = 3 mm., it is not recognizable when the distance K — B = 9 mm., and when K — B = 36 mm.; at 48 mm. it

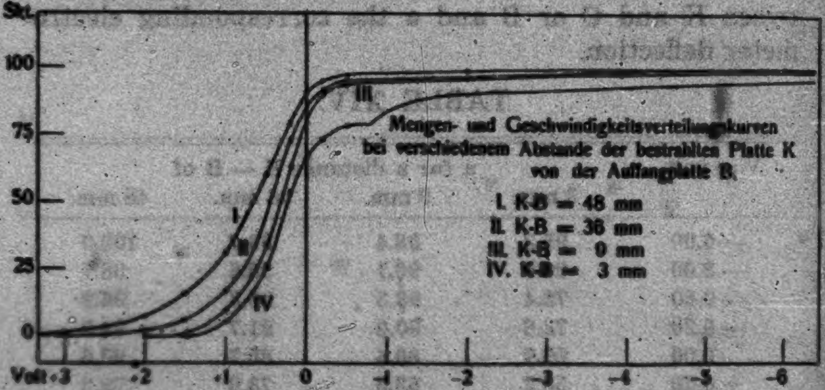

Fig. 14. Tabelle 14.

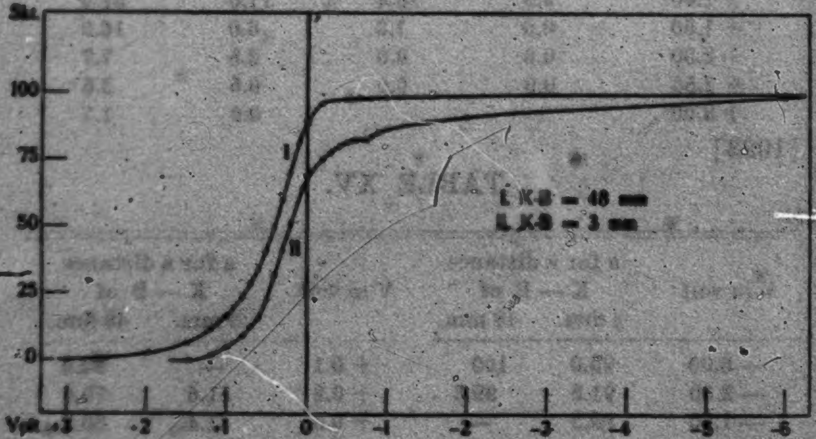

Fig. 15. Tabelle 15.

[1024] entirely disappears. At the same time the rise in radiation behind the zero point (on the negative branch of the curve corresponding to accelerating potentials) considerably decreases while the rise in the positive branch is steeper. This leads to the conclusion that the kink ascertained at first by Lenard is essentially a result of the reflected radiation in opposition to the doubts of Klages. Under no circumstances the appearance of the kink is to be attributed to a process taking place on the illuminated plate, e.g., to formation of double layers on it. For in that case, it is not understood why a mere increase or decrease in the distance between the plates can cause the kink to disappear or to appear. Also a surface force had to have exactly the same effect when the distance was great as when small. That in the experiments of Lenard,[14] Lienhop[15] and Klages,[16] the kink appears with great distinctness, seems accordingly for the most part the result of the small distance between the plates. Lenard and Lienhop used a distance of 5 mm. in the experiments considered here and [1025] Klages only one of 3 mm.

The fact that the kink is essentially the result of the reflection is also confirmed by the following test. If a cap is used which is not a highly polished one, but is covered with soot, the kink must disappear—even when the distance is only 3 mm.—as soot reflects an exceedingly small amount. This is shown in fact by the curves of Figure 16, these being a graphical representation of the results of Table 16.

[1026]

IV. *Results.*

1. A reflected radiation was indicated for low velocities of the rays when the cathode rays were photoelectrically liberated, on which there is superposed a secondary radiation arising rather suddenly when the primary velocity is 11 volts. The latter was continued for a primary velocity up to 500 volts and the point of reversal of Lenard was ascertained at 220 volts.

2. The velocity of the secondary radiation was found to be of the order of 8 volts or smaller; a reflected radiation with a velocity greater than 25 volts was not noticeable.

3. The reflected electron radiation may be made noticeable by a change in form[17] of the quantity and velocity distribution curves. The kink in them first found by Lenard was shown to be the result of reflected electron radiation counter to the doubts of Klages.

The present investigation was carried out at the Physical Institute of the University of Berlin at the instigation and guidance of Professor Doctor Rubens and

Professor Doctor von Baeyer. I am also permitted to present my cordial thanks to my highly honored teacher, Geheimrat Rubens, for the lively interest in my work and the constant assistance in the same. I also owe sincere thanks to the Privatdozents Doctor von Baeyer and Doctor Ladenburg for their manifold advices.

JOHN T. MARSHALL, DECEASED, LATE OF METUCHEN, NEW JERSEY, BY ELIZA T. MARSHALL, EXECUTRIX, OF METUCHEN, NEW JERSEY, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

PROCESS OF EXHAUSTING LAMPS.

1,205,002. Specification of Letters Patent. Patented Nov 14, 1916.

Application filed October [illegible], 1911. Serial No. [illegible].

To all whom it may concern:

Be it known that JOHN T. MARSHALL, deceased, late a citizen of the United States and a resident of Metuchen, in the county of Middlesex, State of New Jersey, during his lifetime invented certain new and useful Improvements in Processes of Exhausting Lamps, and that I, ELIZA T. MARSHALL, executrix under the last will and testament of the said JOHN T. MARSHALL, do hereby declare, to the best of my knowledge and belief, that the following specification, taken in connection with the accompanying drawing, is a clear, true, and complete description of said improvements.

This invention relates to the production of evacuated vessels in which a high degree of vacuum is desired, and more particularly to exhausting incandescent lamps.

When a number of incandescent lamps, particularly metal filament lamps, are exhausted in the usual way, the finished lamps differ considerably in voltage; that is, in the amount of voltage which must be applied to the lamp to cause it to give the candle power for which it was designed. Apparently these variations in voltage are caused to a large extent by heating the filament in the presence of the gases and vapors which are necessarily present as long as the lamp is connected to the pump.

One object of the present invention is to produce an improved process of exhausting which will decrease the difficulties of this kind heretofore encountered.

A further object is to produce the desired vacuum in an incandescent lamp without heating the filament while the lamp is connected to the pump.

A still further object is to regulate more exactly than heretofore the amount of phosphorus vapor evolved in the lamp or vessel which is being exhausted; and in general to improve the production of incandescent lamps and similar evacuated vessels.

To accomplish these objects phosphorus or similar vapor is evolved directly in the lamp or vessel after the lamp has been sealed and is entirely finished so far as [illegible] is concerned. The vapor may be evolved in a vessel or lamp in various ways, but preferably the phosphorus, or some substance which is capable of evolving the desired vapors when heated, is placed inside the vessel or lamp in such a relation to the filament or other current carrying portion of the lamp that when the lamp is sealed off and then lighted at the proper voltage to produce the blue glow, phosphorus vapor is evolved by the heat of the lighted filament, the blue glow disappears, and the vacuum is perfected. The amount of phosphorus introduced into the lamp is controlled very exactly by dipping the mount of each lamp into a solution, or liquid containing suitable material, such as phosphorus. Preferably each mount is dipped to the same extent, while the strength of the solution is kept uniform, and enough of the liquid adheres, especially to the metal of the mount to produce the necessary amount of phosphorus vapor in the lamp bulb when the lamp is lighted. To vary the amount of phosphorus introduced into each lamp the depth of immersion or the strength of the solution may be varied.

The present invention will best be understood in connection with the accompanying drawing, which merely for purposes of illustration shows an incandescent lamp at different stages of the process invented by him, and in which—

Figure 1 shows the mount being dipped into a solution of some substance which will evolve phosphorus vapors when heated; Fig. 2 shows the lamp as connected to the pump, the mount having been coated at the bottom by being dipped, the coating being much exaggerated in order that it may be visible; and Fig. 3 shows the lamp after having been sealed off from the pump and before being lighted for the first time.

In accordance with the present invention there is placed in a vessel or a lamp 1 which is to be exhausted some vapor generating substance, such as phosphorus, which generates when heated a vapor which reacts with the residual atmosphere of the lamp and is capable of improving the lamp and perfecting a "partial" vacuum. The vessel or lamp is then connected to the pump by a tubulature 2 in the usual way and while being pumped out is heated by some external source of heat to such a temperature that occluded gases and vapors are driven out, but the vapor generating substance is not heated enough to cause generation of vapor, as the filament is not heated while the lamp is on the pump. When the vacuum is as high as is usually obtained by pumping when exhausting in the usual way, the lamp or vessel is sealed off at 3 close to the bulb. This operation removes the tubulature and is the last glass-working operation performed on the lamp, which is now finished so far as glassworking is concerned. No portion of the tubulature or any other projection which contained phosphorus must afterward be cut off, as in the customary method of exhausting where phosphorus paint is placed in the tubulature and none of the glass of the lamp need afterward be heated high enough to drive out of it occluded gases or water vapor.

The vacuum produced by pumping is not high enough and is perfected by generating in the lamp or vessel from the vapor generating substance, such as phosphorus some vapor which will react with the residual atmosphere in the presence of the highly incandescent filament and perfect the vacuum, or in some way improve the lamp. This substance, usually some form of phosphorus, may be heated by the filament to generate vapor. In the preferred construction the vessel to be evacuated contains a high resistance, conductor, and the vapor generating substance is placed on or in thermal relation to the conductor so that when sufficient current is passed through the conductor the substance will be heated sufficiently to evolve the vapor.

In exhausting incandescent lamps, the phosphorus vapor is preferably introduced by placing the vapor generating substance on the mount, which is inside the lamp when the lamp is finished and which comprises the metal filament 4, preferably of tungsten, and its supports, such as the glass post 5 and metal anchor or supports 6. This substance is placed on some metal part of the mount in thermal relation to the filament 4 so that lighting the lamp at a voltage which produces a blue glow in the bulb will heat the substance and cause the phosphorus vapor to be generated. This vapor acts as in the usual method of exhausting, and in its presence the blue glow disappears and the vacuum is perfected.

The vapor generating substance may be placed upon the mount in various ways, but, preferably the mount is dipped into a liquid containing the substance, then withdrawn, and the adhering liquid permitted to dry. Practically the whole mount may be immersed in the liquid, wetting the filament and supports, or it may be dipped until only the lower end of the post 5 and the lower metal anchors or supports 6 are immersed, as shown in Fig. 1. The same amount of phosphorus is introduced into each lamp by dipping each mount to a uniform depth into a bath or solution of phosphorus of which the strength is kept uniform. A bath of phosphorus of such a strength that it produces a barely discernible deposit upon the glass of the mount after the adhering liquid has dried is sufficient to perfect the vacuum. The amount of phosphorus introduced into the lamp may be controlled very exactly by varying the strength of the bath or solution or by varying the depth of immersion. This method of introducing phosphorus or similar material into a lamp or vessel may be used to advantage in any method of exhausting which requires the introduction of such material.

Although the mount is preferably dipped into a bath or solution of phosphorus, such as finely divided phosphorus mixed with or dissolved in alcohol, the phosphorus or similar material may be placed upon the mount in other ways, and may be placed anywhere on the filament or on the metal supports for the filament in such a relation to the filament that when, after being sealed off and finished, as shown in Fig. 3, the lamp is lighted for the first time and at a voltage sufficient to produce the blue glow, the hot filament causes sufficient phosphorus to vaporize from the metal to remove the blue glow and perfect the vacuum in the presence of the intensively incandescent filament, without heating the glass of the lamp enough to drive out of it any occluded gases or water vapor.

This invention may be embodied in many other forms than that shown and described and is not limited to the precise arrangement disclosed herein, since various modifications thereof will suggest themselves to those skilled in the art without departing from the spirit of the invention, the scope of which is set forth in the annexed claims.

What is claimed as new and desired to be secured by Letters Patent of the United States, is:—

1. In the manufacture of an incandescent lamp having metal parts comprising a tungsten filament and metal anchors for the filament, the process which consists in applying to metal parts of the mount in position to be vaporized by the heat of the incandescent filament a substance solid at room temperature but reacting with the residual atmosphere to improve the lamp when vaporized in the presence of the incandescent filament, exhausting the lamp without heating the filament, sealing off the lamp, and then for the first time passing current through said filament to vaporize said substance and produce an atmosphere containing the vapor of said substance conjunctively with intensive incandescence of said filament while all glass of the lamp is below the temperature at which occluded gases are driven out of it.

2. In the manufacture of an incandescent lamp having metal parts comprising a tungsten filament and metal supports for the filament, the process which consists in applying phosphorus to metal parts of the mount in position to be vaporized by the heat of the incandescent filament, exhausting the lamp to a predetermined degree without heating the filament, sealing off said lamp, and subsequently raising said filament to intensive incandescence to vaporize the phosphorus while all the glass of the lamp is below the temperature at which occluded gases are driven out of it.

3. In the manufacture of an incandescent lamp having a mount comprising a metal filament and metal anchors, the process which consists in wetting the metal of the mount to a predetermined extent with a liquid having uniformly distributed through it a definite percentage of a substance solid at room temperature and vaporizable by incandescence of the filament, drying the metal to leave on it a coating of the solid substance, exhausting the lamp containing the coated metal without heating said filament, sealing off the lamp and then for the first time passing current through said filament to vaporize said substance and raise said filament to intensive incandescence conjunctively with the generation of said vapor while the glass of the lamp is below the temperature at which occluded gases are evolved.

4. In exhausting incandescent lamps, having mounts comprising metal filaments and metal anchors, the steps of introducing the same amount of phosphorus into each lamp by dipping the corresponding metal parts of all the mounts to the same extent into a liquid having phosphorus uniformly distributed through it, drying the metal parts to leave a coating of phosphorus on them, pumping out the lamp without heating the filament, sealing off the lamp, and then for the first time passing current through the filament and raising it to intensive incandescence.

5. The steps in the manufacture of a tungsten filament incandescent lamp which consist in coating at least a part of the tungsten filament with a substance solid at room temperature and reacting with the atmosphere in the lamp when vaporized in the presence of the incandescent filament to improve the lamp, exhausting and sealing off the lamp without vaporizing said solid substance, and then for the first time passing current through the filament to vaporize said substance and render said filament intensively incandescent in the vapor of said substance while the glass of the lamp is below the temperature at which occluded gases and water vapor are driven out of it.

In witness whereof, I have hereunto set my hand this seventeenth day of October, 1911.

ELIZA T. MARSHALL,

Executrix of the estate of John T. Marshall deceased.

DISCHARGE FROM HOT CAO.

By C. D. Child.

It was suggested a few years ago by Sir J. J. Thomson[1] that certain phenomena of electrical discharge could be explained by what we may call ionization by *repeated* impact. He had found that luminous discharge could be produced from a cathode of hot CaO with potential differences much smaller than those which are needed when a cold cathode is used, and that at a certain critical point it needed but a very small increase in the voltage to produce a large increase in the current and to change from the non-luminous to a luminous form of discharge. He believed that the ionization in the luminous form of discharge was not due to the breaking up of an atom by a single impact with an electron, but rather to an explosion of the atom because of its having absorbed so much internal energy from repeated impacts with electrons that its equilibrium had become unstable.

If this idea is correct, it is important not only because it explains this particular phenomenon, but also because it offers an explanation of the ionization of the arc and gives us some information concerning the character of the atom. I have, therefore, given some study to the subject, but find that there are several reasons for rejecting this explanation.

Improbability of Repeated Impacts.—The first of these objections is that there are far too few electrons present in the tube at any time before the discharge becomes luminous to occasion repeated impacts. For example, in one experiment performed by myself the largest current that could be passed through the tube without having a luminous discharge was 5×10^{-8} ampere, which is 150 electrostatic units. The charge carried by each ion[2] is 3.4×10^{-10}. The cross section of the tube used was approximately 5 sq. cm. So that the number of electrons passing through each square centimeter per second was 8.85×10^{10}. The pressure of the gas was .014 mm. and the mean free path of the electron at this pressure is approximately 3.76 cm.[1] So that in each cubic centimeter only 2.34×10^{10} electrons would hit molecules per sec.

---

[1] Nature, 73, 496, 1906.

[2] Thomson's Conduction of Electricity through Gases, 2d ed., p. 158.

According to Myers[2] there will be 11.2×10^{14} molecules per c.c. under these condition of pressure and temperature. From this we find that each molecule will on the average be hit once in 48,000 sec., or once in thirteen hours, and it only requires a fraction of a second to produce the luminous discharge when the conditions are right for it.

This is, of course, not an argument against ionization by repeated impact after the luminous discharge has commenced, for then the number of electrons will be very much greater, but the idea of such impact was used by Thomson as an explanation of the beginning of the luminous discharge, and it is an argument against such an explanation. There will, however, be other data given later which indicate that not at any time is there ionization by repeated impact.

Critical Condition Does not Depend on the Amount of Current, but on the Condition of the Cathode.—In the second place experiments indicate that the voltage required to change from the non-luminous to the luminous discharge depends but slightly, if at all, on the amount of current flowing, but does depend very greatly on the kind and condition of the cathode. That is, the number of electrons passing through the tube and hitting upon the molecules does not determine the point where the change occurs, while other conditions do.

The form of apparatus used for showing this is given in Fig. 1. *T* is a tube 2.8 cm. in diameter. *P* is the connection to the vacuum pump, McLeod gauge, and drying tube. *C* is the cathode consisting of platinum foil, approximately 2 mm. in width, 12 mm. long, and .02 mm. thick, the bottom being covered with CaO. This was welded to aluminum wires which led out of the tube and was heated by an alternating current connected at *c* and *c'*.

A is an iron anode, fastened to an iron wire which is brought down through the tube *a* into a mercury cup, so that the anode could be raised or lowered. A shunt of 50 ohms resistance was placed across *cc'*. The middle of this, lettered *b*, had the same potential as the middle of the foil *C*. A potential difference was maintained between *b* and *A* by connecting them to *d* and *d'*, two points on a variable resistance through which a current was passed from a dynamo. By this means any potential difference from 0 to 130 could be used. *V* is a Weston voltmeter measuring this potential difference. *G* is a galvanometer measuring the current through the tube.

[2] Myers' Kinetic Theory of Gases, p. 333.

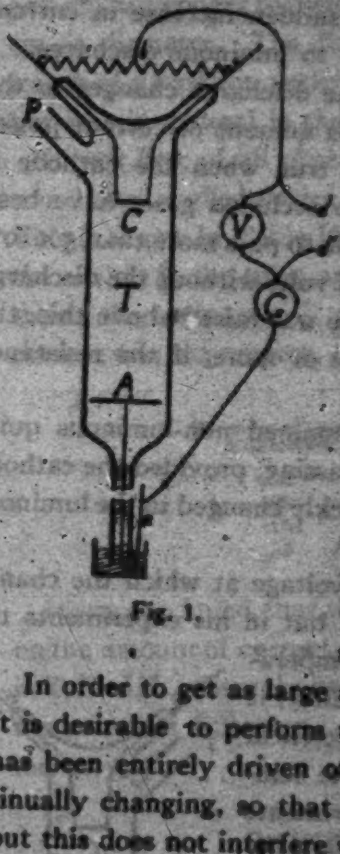

Fig. 1.

The first experiment was a comparison of the discharge from clean hot platinum with that from hot platinum covered with CaO. With clean platinum it is possible to get a large current without changing the character of the discharge, while with CaO it requires but a very small current to produce this change, the potential difference between the electrodes being the same in the two cases.

In order to get as large a current from the platinum as possible it is desirable to perform the experiment before the occluded gas has been entirely driven off. If this is done, the current is continually changing, so that no two sets of readings are the same, but this does not interfere with our present purpose.

The readings as taken are given in Table I., the first column giving the potential difference between the electrodes and the second the current. The platinum foil was a little more than red hot and the pressure of the gas was approximately .04 mm.

TABLE I.

Potential Difference in Volts.	Current in Amperes Times 10^{-7}.
71	.1
80	.5
84	2.1
90	6.5
125	48.2

There was here no abrupt change in the amount of current and the discharge was not at any time luminous. There is in some cases a slight luminosity with the discharge from clean platinum, but even then there appears to be no sudden increase in current nor sudden change from non-luminous to luminous discharge.

On the other hand with hot CaO the discharge changes to the luminous form before anything like this amount of current passes through the tube. This is especially true when the cathode is quite hot and has been used until the occluded gases have been driven off. In one case it was impossible to pass more than 5×10^{-6} ampere with a potential difference of 95 volts without the discharge becoming luminous. When the voltage was raised above this, the current became as large as an ampere or more, if the resistance in series with the tube was small.

Thus we see that the discharge remained non-luminous quite irrespective of the amount of current passing, provided the cathode was clean platinum and that it very quickly changed to the luminous form, if the cathode was very hot CaO.

Thomson states that he found the voltage at which the change took place to depend on the current, but in his experiments the current was changed by raising the temperature of the cathode. When that is done, it is not possible to decide whether the critical point depends on the current or on the temperature of the CaO. In the experiments described above it is made clear that it is the condition and temperature of the cathode that determines this point and not the amount of current.

The Potential Difference between the Beginning and End of a Striation.—The potential difference between the beginning and end of a striation was examined, hoping that it would throw some light on this question.

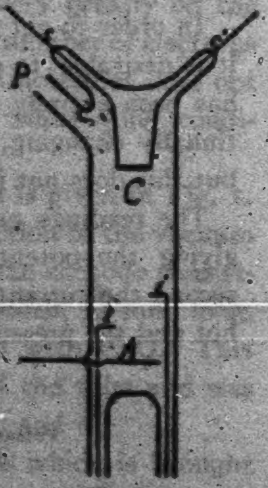

Fig. 2.

The tube was exchanged to the form shown in Fig. 2. Both *A* and *C* are here fixed; *e* and *e'* are two movable exploring electrodes which are connected to an electrometer. The vertical parts of these were covered with small glass tubes for a few centimeters near the top, so that only the horizontal ends would receive charges. These ends were platinum wires .5 mm. in diameter. They were placed as near as possible to the sides of the tube and did not appear to distort the striations. The main tube was 4.2 cm. in diameter. The distance between *A* and *C* was 8 cm. The length of a striation varied as the pressure of the gas was varied, but was in general in the neighborhood of 2.5 cm.

It was first of all observed that the potential difference which was being studied varied as the pressure of the gas was changed. This is shown in Table II. The first column gives the pressure of the air left in the tube, and the second the potential difference between the beginning of one striation and that of the next. The current was .02 ampere.

TABLE II.

Pressure of Gas in Millimeters.	Potential Difference in Volts.
.06	11
.08	12.9
.164	16
.38	21.5

It was also found that the striation potential difference depended on the amount of current flowing through the tube. This is shown in Table III., where the first column gives the current and the second the potential difference. The pressure in the gas was .06 mm. of mercury.

TABLE III.

Current in Amperes.	Potential Difference in Volts.

.00064	13.2
.01	12
.2	10

Since these experiments were performed an article has been published by Wehner,[1] giving the results of a full investigation of the striation potential difference when there was discharge from a cold cathode. His experiments on the change produced in this quantity when the pressure of the gas was changed were performed in hydrogen and the potential differences which he gives are lower than the ones given above, but they show the same kind of a change.

---

[1] Ann. d. Phys., 32, 49. 1910.

In general he also found the same kind of a change when the current was changed. The changes, however, were through a much smaller range than that given here and were accordingly less noticeable. The lowest value which he found for the potential difference was 8.56 volts.

At first sight Table III. appears to give some reason for believing that ionization may take place more easily where there is a chance for repeated impact. Certainly it is true that where there is the greatest number of electrons passing through a gas, there is the smallest striation potential difference, and it is probable that this quantity is closely related to the potential difference needed to produce ionization by impact, as is suggested by Wehner.

But a second thought will hardly encourage such a view. The current was six hundred times greater in the last case given in the table than in the first. Each molecule would be hit six hundred times in one case where it would be hit but once in the other, and yet the potential difference decreased but a few per cent. It is certainly highly improbable that such a small change would occur, if repeated impact causes the molecules to be more easily ionized.

Certainly it is possible to suggest some more probable explanation. For example, when the larger current is flowing, the temperature of the gas must be much above that of the room. A small percentage of the electrical energy dissipated in the tube would be sufficient to raise the temperature of the gas several hundred degrees in a few seconds and it is altogether probable that at high temperatures the gas is more easily ionized than at low ones.

However, we will not be ready to give any explanation of these facts until we know more about what the facts are. For example, the lowest voltage here recorded was 10 volts, but Thomson states[1] that he found the potential difference between one striation and the next to be as low as 2.7 volts under certain conditions. He does not state what these conditions are, and I have not been able to get such a value. But until the phenomena have been more thoroughly examined, it is not possible to state what the cause of the relation between the voltage and the current is, and certainly we cannot say that these phenomena uphold in any way the idea that ionization occurs more easily when there is repeated impact.

---

[1] Phil. Mag., 6, 18, 449, 1909.

Increase in Current not due Alone to Ionization in the Gas.—We have given reasons for believing that the change from the nonluminous to the luminous form of discharge is not due to ionization by repeated impact. We may go a step further and say that the change does not appear to be due alone to ionization of any kind in the gas. There is no question but that ionization by impact occurs, but there are reasons for believing that it is not the only cause producing the change.

There are two ways in which ionization in the gas can increase the current. It can increase the number of positive ions moving toward the cathode, or it can change the field near the cathode, so that all the electrons shall be drawn from it, instead of being driven back by the electrostatic repulsion of those which had previously been emitted.

That the great increase in the current cannot be accounted for by a movement of positive ions toward the cathode is shown by two lines of reasoning. The first is that the electrostatic effect on the positive ions would check any large increase in the current due to them alone.

The Electrostatic Effect Produced by Ions.—An electrostatic effect occurs whenever there are more ions of one kind than of the other in a given volume. This effect may become so large as to reverse the previous direction of the field and to limit very greatly the amount of current flowing. This is especially apt to occur when there are positive ions present, for their mass is much greater than that of the negative ions and their motion correspondingly slower.

The ratio of the mass of positive ions to their charge is approximately 20,000 times as great as the corresponding ratio for the negative ions.[1] As a result one positive ion going through a given space per second would neutralize the effect of 20,000 electrons. If there were more positive ions than this they would raise the potential of the region and tend to check their own movement. It is not possible to compute just how many positive ions it would take to raise the potential so as to check the current when the cathode is an irregular piece of foil, but we may get some idea of what is to be expected by considering the current density between parallel plates of infinite extent, when there are only positive ions present. The less the ions are stopped by collisions with molecules, the greater will be their velocity and the less the electrostatic effect produced by the movement through the field of a given number. In order to find the maximum current, we may assume that there are no collisions. I have not been able to find any computation applying to this case, and hence have given it in the following paragraphs.

---

[1] Thomson's Conduction of Electricity through Gases, 2d ed., p. 149.

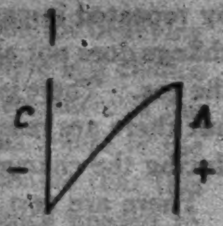

Fig. 3.

Let us assume that the plates A and C are of infinite extent, separated by a distance x_1. Let the potential of C be zero and that of A be V_1, and assume that there are at A an indefinitely large number of positive ions. The electric force will cause these to move toward C, producing a current.

Let I = the current flowing through a unit cross section,
n = the number of ions in a unit volume,
e = the charge in electrostatic units carried by each ion,
m = the mass of each ion,
V = the potential in electrostatic units at any point at a distance x from C,
v = the velocity of the ions at a distance x from C,
ρ = the density of the electricity at a distance x from C.

$I = nev$ = a constant, and the acceleration of the ions equals the charge times the electric force divided by the mass, or

$$\frac{dv}{dt} = -\frac{e}{m}\frac{dV}{dx}$$

If we multiply this equation by the equation, $vdt = dx$, and integrate, remembering that the velocity is zero when V is V_1, we have

$$\frac{1}{2}v^2 = \frac{e}{m}(V_1 - V) \qquad \text{or} \qquad v = \left\{\frac{2e}{m}(V_1 - V)\right\}^{\frac{1}{2}}.$$

But

$$\rho = ne = \frac{I}{v} = \frac{I}{\left\{\frac{2e}{m}(V_1 - V)\right\}^{\frac{1}{2}}},$$

and if we assume that there is no variation in potential in directions parallel to the plate we have

$$\frac{d^2V}{dx^2} = -4\pi\rho = -\frac{4\pi I}{\left\{\frac{2e}{m}(V_1 - V)\right\}^{\frac{1}{2}}} = -\frac{k}{(V_1 - V)^{\frac{1}{2}}}$$

where k is a constant equal to $4\pi I/\sqrt{2e/m}$.

Multiplying this by the equation

$$\frac{dV}{dx}dx = dV$$

and integrating, we have

$$\frac{1}{2}\left(\frac{dV}{dx}\right)^2 = 2k(V_1 - V)^{\frac{1}{2}} + C.$$

The constant, C, equals the value of $\frac{1}{2}(dV/dx)^2$ at A. As the space between A and C becomes more and more filled with positive ions, the value of dV/dx approaches zero, and for the largest current which it is possible to have it would equal zero. For such a current we have

$$\frac{dV}{dx} = 2\sqrt{k}(V_1 - V)^{\frac{1}{4}}.$$

Further integration gives us

$$V = V_1 - (V_1^{\frac{3}{4}} - \tfrac{3}{2}\sqrt{k}\,x)^{\frac{4}{3}},$$

since $V = 0$ when $x = 0$. The curve in Fig. 3 between A and C represents such a distribution of potential as this.

Since V_1 is the value of V when $x = x_1$, we have

$$\tfrac{3}{2}\sqrt{k}\,x_1 = V_1^{\frac{3}{4}}$$

$$I = \frac{1}{9\pi}\sqrt{\frac{2e}{m}}\,\frac{V_1^{\frac{3}{2}}}{x_1^2}.$$

In other words, this is the largest current which it is possible to have carried by positive ions with the given distance and the given potential difference between the plates.

The value of e/m for positive ions in electrostatic units is approximately 12×10^{11}.[1] If for example we take one third of an electrostatic unit (100 volts) for the potential difference between *A* and *C* and the distance 4 cm., the current would be 2.08×10^3 electrostatic units, or 7×10^{-7} ampere. This is the amount of current which could be carried if there were only positive ions, or the amount carried by the excess of positive ions. A certain amount might be carried by negative ions, a second small amount by the positive ions which would be needed to neutralize the electrostatic effect of these negative ions and the amount given above would be the greatest possible additional amount which the excess of positive ions could carry.

---

[1] Thomson's Conduction of Electricity through Gases, p. 149.

The potential difference and distance assumed are similar to those existing in the experiments which have been described. The shapes of the electrodes in the experiment were indeed quite different from those considered in the mathematical treatment. But when we remember that it was possible to have an increase of nearly an ampere per sq.cm. a few centimeters away from the cathode and of many times this density of current near the cathode, we can see how improbable it is that any such increase in the current was carried by positive ions coming from the gas.

But an even more convincing reason for believing that the increase in current is not produced by a movement of the positive ions toward the cathode is given by the appearance of the luminous discharge. With non-luminous discharge there were, of course, no streams of cathode rays which could be detected. With the luminous discharge there were very noticeable cathode rays, appearing as brilliant streamers extending from the cathode to the sides of the tube or down into the gas. That these were cathode rays was shown by the effect which a magnet had upon them and by the phosphorescence which they produced. One could hardly see these streamers without realizing that something had happened to increase enormously the number of electrons leaving the cathode.

Increase in Current not due to Change in Field.—While the increase in current cannot be due to the movement of positive ions, it is conceivable that it is due to a change in field produced by them. When there is no ionization of the gas, the electrons coming from the cathode may be so numerous as to reverse the direction of the field in part of the space and hold back other electrons which might be leaving the CaO. That this actually could occur is shown by the data given in Table IV. When there are also positive ions in the field, they may so neutralize the effect of the electrons, that all the electrons which escape from within the CaO will pass to the anode. In order to consider this possibility the potential between the electrodes was examined both with non-luminous and with luminous discharge.

Potential between the Electrodes.—The apparatus shown in Fig. 2 was used to measure the potential between the electrodes, and since only one exploring wire was needed, e' was removed.

There are given in Table IV. a series of readings of the potential between *A* and *C* taken when the cathode was a dull red and a non-luminous current of 1×10^{-8} ampere was passing through the tube. In Table V. there is given a similar set taken with a luminous current of .03 ampere. In both cases the pressure of the gas was .02 mm. This was so low that there were no striations nor anode glow between the electrodes. The potential difference between *A* and *C* was 90 volts, and the distance 8 cm. Column one gives the distance from *C* and column two the potential difference between *C* and the exploring electrode as measured by an electrometer.

TABLE V.

Distance from Cathode in cm.	Pd between *C* and *e* in Volts.
.3	71
2.	71
4.	69
6.	69
7.	66

The first value in Table IV. indicates that the potential of the gas near the cathode was slightly lower than that of the cathode itself. This is due to the tendency of the CaO to give out electrons faster than the field draws them away, in fact to emit them against a small electric field, as has been pointed out by Richardson.[1]

---

[1] Phil. Mag., 6, 16, 354, 1908.

In the second case the same kind of an effect occurs except that here the electric force is reversed not near the cathode but a few centimeters from it. This fact has been observed by Thomson.[1] The momentum of the ions is such that it carries them for some distance against the opposing field.

The potentials here given are much lower than those given by Westphal.[2] He was undoubtedly working with much higher temperatures than those existing in these experiments.

These results are plotted in Fig. 4, the first curve showing the potential when the discharge was non-luminous and the second when it was luminous. With the first one there is an excess of negative ions between the electrodes, with the second an excess of positive. In the first case there is little or no ionization in the gas, while in the second there is a large amount. This might at first lead one to think that the difference between these two forms of discharge was entirely due to the presence of the positive ions near the cathode and the resulting drop in potential at that point. For this would cause all of the electrons which might escape from within the CaO to pass through the tube, but further light is thrown on the matter by examining the potential between the electrodes when discharge is passing from clean platinum.

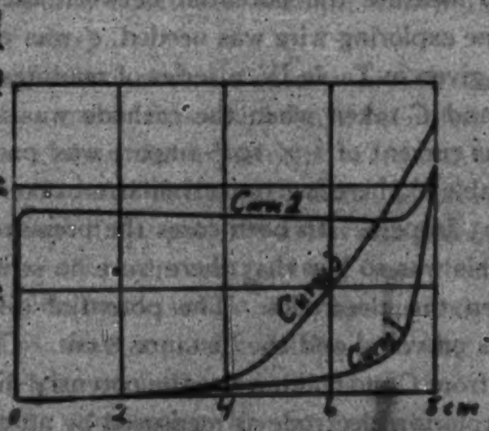

Fig. 4.

For this purpose clean platinum was substituted for that covered with CaO and observations were taken with the platinum heated to a bright red. The potential difference between the electrodes was 90 volts and the current through the tube was 5×10^{-7} ampere. The potential at different points was found to be approximately the same as those given in Table IV., when there was non-luminous discharge from CaO.

TABLE VI.

Distance from Cathode in cm.	Pd between C and a in Volts.
.3	−1.
2	− .4
4	4.5
6	42.
7	70.

These data are plotted in curve three, Fig. 4. There is here little change between this curve and that found with small currents as far as the space near the cathode is concerned, but a large change near the anode. There is apparently ionization of the gas near the anode, but not enough positive ions are produced to change the potential of all the space.

By raising the temperature of the platinum still higher a current of 4.8×10^{-4} ampere was passed through the tube. The potential in the neighborhood of the cathode was unchanged, while that in the neighborhood of the anode was still further raised. For example, the potential 6 cm. from the cathode became 68 instead of 42 volts.

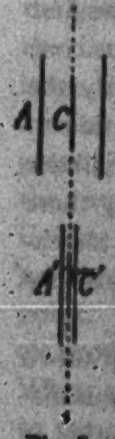

Fig. 5.

It is apparent that this form of discharge is not the same as either the non-luminous or the luminous form of discharge from CaO, since we have some ionization of the gas and yet there is no great change near the cathode. Apparently something besides ionization in the gas is needed in order to produce this change.

Some Ionization of the Gas Necessary.—While something besides ionization of the gas appears to be necessary in order to change from the non-luminous to the luminous discharge, it is also necessary that there should be this ionization, as is shown by the following experiment.

Two pieces of platinum wire, C and C' in Fig. 5, are surrounded by brass cylinders of different diameters and placed in a vacuum

450

tube. Both wires were .5 mm. in diameter, had the same length and were heated by the same current. They were coated with CaO and were made the cathode with the cylinders as anodes. The smaller cylinder was 4.85 mm. and the larger 23 mm. in diameter. Both were 4.5 cm. in length. The potential difference between the wires and the cylinders was in all cases 90 volts. There are given in the following table the currents to the cylinders with two different pressures of the gas.

TABLE VII.

Pressure of Gas in mm.	Current to Small Cylinder in Amperes.	Current to Small Cylinder in Amperes.
.35	.01	8×10^{-3}
.014	5.8×10^{-6}	1.6×10^{-3}

This shows that the current to the small cylinder decreased very much when the pressure of the gas was diminished below a certain amount, and that at the same time the current to the large cylinder increased. The number of electrons coming from within the CaO was no doubt the same for both wires, and the electric force was, of course, in both cases larger for the small cylinder. In the first case the discharge to the small cylinder was the larger, as one would expect, since the electric force was larger. Apparently the small discharge to the small cylinder in the second case is due to the fact that there were then so few molecules within the cylinder that there was less opportunity for impact and consequently there was little ionization. It would, therefore, appear that while ionization of the gas is not the only requirement, it is at least a necessary requirement.

The Correct Explanation.—It has already been stated that much smaller potential differences are adequate to produce luminous discharge from hot CaO than from any cold cathode, but this is practically the only difference between the two cases. In both the luminous discharge commences with great suddenness and in both there are streams of electrons shooting out from the cathode. It would, therefore, seem as if some modification of the explanation which Thomson has given for the ordinary discharge in a vacuum would come nearer the truth than that which was suggested.

His explanation for such discharge is briefly as follows: The current through the tube is carried by ions. The production of these is a two-fold action. Negative ions which have been driven off from the cathode hit the molecules of the gas and ionize them by their impact. The positive ions thus formed are drawn up to the cathode and ionize the molecules at the surface of the cathode by their impact on them. The negative ions thus formed repeat the process by ionizing more molecules of the gas. The electric force in the tube must be sufficient to produce ionization at both of these places, but since it requires a much higher potential difference to ionize by the impact of the positive ions, it comes about that the critical potential difference is reached when such ionization begins.

It is altogether probable that the same thing occurs in the case of discharge from hot CaO, the only difference being that the molecules on the surface of the hot CaO are more easily ionized than those on the cold cathode, and there are reasons for believing that this is true, as will be given shortly.

If we make this assumption the phenomena may be explained as follows: As soon as the electric force is great enough to ionize the gas, we have a slight increase in current, such as is shown with the discharge from clean platinum. This increase does not become large, unless the positive ions thus formed are able in turn to produce ions by impact on the surface of the CaO. When this occurs, the greater the number of positive ions formed in the gas, the greater the number bombarding the cathode with the corresponding further increase in the number of electrons sent off. There is thus produced the sudden change in current which occurs at the critical point. This change is limited by the rise in potential between the electrodes which is caused by the presence of the positive ions. When this increase becomes so large that the ions are not carried to the electrode as fast as formed, the current remains stationary.

This sudden increase is probably helped by the fact that the rise in potential in the tube causes the principal drop in potential to be near the cathode, instead of near the anode. The electrons coming from the cathode have a certain velocity when first emitted. A drop in potential in its immediate neighborhood increases this and produces a greater final velocity than if applied to electrons which might be starting from rest at some point in the gas.

There are the following reasons for believing that the molecules on the surface of the cathode are more easily ionized by impact of positive ions when the cathode is hot than when cold. Due to their high temperature they are already in unstable equilibrium, as is shown by their sending out electrons even when not being bombarded. One would in fact be surprised, if it did not require a smaller momentum in this case to produce ionization than when the molecules are at a low temperature.

Secondly it has been shown by Hittorf[1] and Cunningham[2] that heating the cathode causes the cathode drop to become smaller.

Furthermore I have found that the higher the temperature of the CaO the less the cathode drop in its neighborhood. The drop given in Table V. was 71 volts, but when the temperature of the CaO was raised, this decreased rapidly. When heated as much as practical without melting the platinum foil, the cathode drop was only 8 volts.

Increasing the current through the tube also decreased the cathode drop but only to a slight extent. Thus in one case the current was varied from .02 to .4 ampere by changing the voltage at the terminals of the tube, the heating current through the foil remaining constant, and the cathode drop varied from 30 to 21 volts. The same change could be made by a very slight increase in the current heating the foil, and it is altogether probable that this change was due to the increase in the temperature at the surface of the cathode caused by the increased bombardment of the cathode and not by repeated impact on the molecules of the CaO.

Production of Electrons by Bombardment of CaO with "Canal-strahlen."—In addition to this it was shown that electrons may very easily be produced when CaO is bombarded with positive ions in the form of "canal-strahlen." It has already been shown by Austin[3] that when such rays strike a metal plate electrons are produced, but it seemed well to investigate the phenomena which exist when they strike hot CaO under conditions somewhat similar to those which held in the preceding experiments.

[2] Phil. Mag., 6, 4, 684, 1902.

[3] Phys. Rev., 22, 312, 1906.

For this purpose the tube given in Fig. 6 was used. An opening was made in the side of the tube shown in Fig. 1, and a second tube, T', was sealed into this. This had a cathode, C', and an anode, A', the distance between them being 9 cm. The anode, A', was a metal disk filling the inside of the small tube and having an opening of 2 mm. in diameter in the center. A discharge could be sent through this tube by means of a Wimhurst machine or an induction coil at I and with proper pressure of the gas "canal-strahlen" would hit on the cathode, C. The anode A' was kept at the same potential as C by connecting it to the point b shown in Fig. 1.

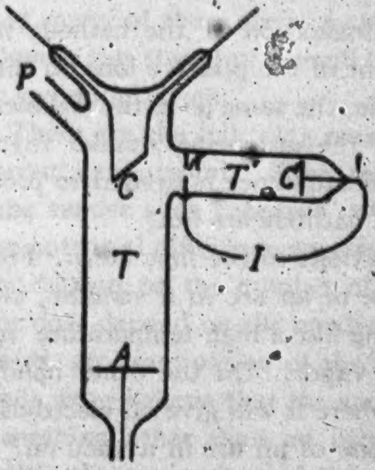

Fig. 6.

With this arrangement C was heated by passing a current through it as in the preceding experiments and a potential difference was established between A and C somewhat below that needed to cause the luminous discharge. If then a discharge was caused to pass from A' to C' so that the "canal-strahlen" hit upon C, luminous discharge would start up in T. With potential differences of about 70 volts this discharge would pass as long as C was being hit by these rays and would stop as soon as the rays would stop.

With larger voltages a continuous arc was often formed. With lower voltages the discharge between A and C was non-luminous but still considerably larger than what it was when there were no "canalstrahlen."

It was found that it was not even necessary to heat C. When C was at the room temperature, and the voltage was approximately 100 volts, the positive rays striking on C caused a luminous discharge between A and C to flash out for an instant. This luminous discharge showed striations the same as those usually produced by hot lime, and if the resistance in series with A was sufficiently small, the discharge became an arc.

Relation between this Work and the Theory of the Electric Arc.—

The work which has been described has an important bearing on the theory of the electric arc. There is no question but that the ionization at the cathode is the essential phenomenon of the arc, but there are two views concerning the cause of this ionization. According to Stark[1] and Thomson[2] the electrons are driven out of the cathode because of its high temperature in the same way as discharge is produced from hot platinum wire. The bombardment of the cathode by the positive ions heats it, but does not directly cause the ionization.

According to the other view the ionization at the cathode is produced directly by the bombardment of the positive ions on the molecules on the surface of the cathode, the same as in the Geissler tube discharge, the cathode drop in the arc being smaller than elsewhere, because a smaller potential difference is needed to produce ionization when the molecules of cathode are hot.

There are some rather serious objections to the first view. For example, mercury can be the cathode of an arc in a vacuum, although it cannot be raised to anything like a high temperature in a vacuum without changing it to a vapor. On the other hand, iron can easily be heated to a point where it will give off electrons, and yet it cannot be made the cathode of an arc in a vacuum.[3]

In addition to these arguments the work which is here described furnishes a further argument in favor of the second view. The arc is apparently the same form of discharge as that which we have been studying, for it has been shown[4] that it is possible to pass by gradual changes from the luminous discharge produced by hot CaO to that of the electric arc. The only essential difference between the two is that in the arc the current through the gas heats the cathode sufficiently to maintain the temperature of the cathode, while in the other form the temperature must be maintained by some outside source, and this difference has nothing to do with the manner in which the ions are produced.

We are, therefore, safe in saying that the weight of evidence is in favor of the view that the ionization at the cathode of the arc is not caused by the high temperature of the cathode, but by the impact of positive ions on the hot surface.

Summary.—When the potential difference between the electrodes is increased the discharge in a vacuum from hot CaO passes through a critical condition, the current being very much greater after the critical point is passed and the discharge becoming luminous. It has been suggested by Sir. J. J. Thomson that this sudden change is caused by the molecules having been hit so often by the electrons that many of them are in a state of unstable equilibrium, and that when in this state but a small increase in the electric force is needed to cause ionization.

There are the following reasons for thinking that this is not the correct explanation. First, the scarcity of electrons present in the tube render such repeated collisions very improbable. Secondly, the potential difference necessary to cause this sudden change does not depend on the number of electrons passing through the tube but does depend on the condition and temperature of the cathode. Third, an examination of the potential gradient through the tube leads us to believe that the sudden increase in current is caused by something other than an increase in the ionization in the gas. Lastly the appearance of the discharge indicates very plainly that the number of electrons streaming from the cathode increases enormously when the discharge becomes luminous, becoming in fact very noticeable streams of cathode rays. On the other hand, some ionization of the gas appears to be necessary as is shown by the fact that, when the pressure of the gas is very low, the discharge from a wire coated with CaO to a small surrounding cylinder is much smaller than that to a large cylinder.

The phenomena may be explained by asssuming that ionizaton is produced at the cathode by the bombardment of its surface by positive ions and that such ionization occurs very much more easily with a very hot cathode than with one which is cold.

The potential difference between the beginning and end of a striation was found to increase as the pressure of the gas increased and to decrease slightly when the current was increased. It was in certain cases as low as 10 volts.

Because of the similarity between this form of discharge and the electric arc, it is reasonable to assume that the electrons at the cathode of the arc are also produced by bombardment of the cathode by the positive ions which come from the gas, and that they are not to any great extent emitted from within the cathode because of its high temperature. Such an explanation accounts for certain difficulties which may be raised against any other explanation.

ON ELECTROMAGNETIC WAVE INDICATORS BASED ON THE PRINCIPLE OF ELECTRONIC EMISSIONS FROM INCANDESCENT WIRES

[235]

A certain category of indicators of electromagnetic waves utilizes apparatus over which perturbations or electric waves produce passage of electricity dissymetrically with respect to the direction of the instantaneously generated electric charge. Thus, under the action of the waves, we finally obtain direct current for which it is much easier to construct very sensitive indicators. In this category, besides others well known, we have the indicators which untilize the passage of uni-directional electricity produced by incandescent filaments, for example, the Fleming valve and the audion of DeForest.

The scope of this note is particularly to study these last two indicators in order to be able, in the succeeding note, to consider a new type which, while also founded on the utilization of the same phenomenon, is characterized by the fact that the effect is independent of the nature of electric impulse (generated by the perturbation or by electric waves) and of the sign of the impulse itself. This new indicator has, in certain cases, sensitivity of action notably superior to that of the indicators heretofore known. It will briefly consider the history of the phenomena which have led to the realization of these types of indicators.

That the air becomes a conductor of electricity in the neighborhood of hot bodies was already known, and we owe to Becquerel to have demonstrated that, even at red heat, it dissipates the charges due even to a small fraction of a volt. Later on Guthrie was the first to begin to show that the phenomenon depended also on the direction of the current. We owe also to Elster and to Geitel (1882-1889) a systematic study which has thrown considerable light on the phenomenon in question. From this study, it results that a hot platinum wire throws off electric charges which, at ordinary pressures, are positive, and at lower pressures, negative. There is, therefore, a certain *pressure of inversion* which depends besides on the nature and the temperature of the wire, on the nature of the surrounding gas, and on the state of occlusion of the gas on the part of the wire itself. We can also speak of *temperature of inversion* since, with pressure constant and temperature increasing, the filament emits charges which pass gradually from the positive to the negative side.

The so-called *Edison phenomenon* is nothing but a particular case, even though sufficiently complex, of the [236] general phenomena which I am considering. It consists, as noted, in the passage of a continuous current through the rarified gas contained in an incandescent bulb, comprising besides the filament, a cold metallic plate. The latter is connected externally with the positive end of the filaments, and the current passes in the rarified gas from the plate to the filament. In consequence of the indicated disposition of the apparatus, the negative end of the filament presents, with respect to the plate, a negative charge which, disposing itself in part as a cause of the electronic emission, gives rise to the above mentioned current. J. J. Thomson, in his book on The Conduction of Electricity Through Gases, discusses many views of experimental and theoretical character on this subject, and from these views, there results, in the case of the dissipation of negative charges from the heated filament in the rarified gas, that it is actually a phenomenon of emission of particles, similar in all respects to that constituting cathode rays; in fact, the ratio between the charge and the mass of these particles or electrons is the same as that which we find in the above mentioned cathode rays.

The passage of electricity through a rarified gas, determined by the presence of a heated filament, is not characterized solely by the uni-directional quality of the phenomenon (emission of negative particles); it departs from the simple linear law. An e. m. f., gradually increased, gives rise to the passage of negative electricity from a filament to a plate enclosed in the same globe of rarified gas, in a manner more rapidly increasing than the law of Ohm would allow. The current thus generated becomes almost stationary for higher values of the e. m. f., if, as J. J. Thomson notes, the value of this e. m. f. be not capable by itself of producing ionization in the gas. There is, therefore, a certain *intensity of saturation* beyond which it is not possible, however, the acting e. m. f. be increased, to augment the current of negative electrons leaving the hot filament.

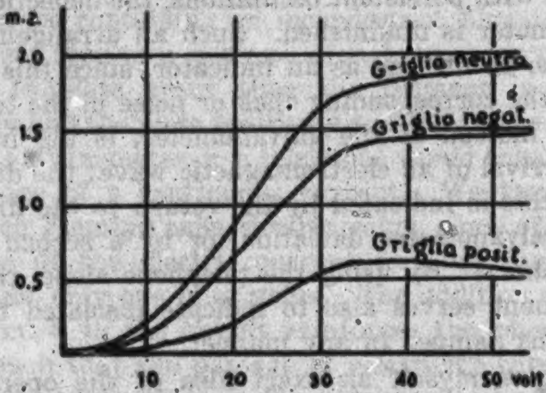
From this rapid review, we recognize how complex is the phenomenon of the electronic emission on the part of hot filaments. Many elements contribute to the variety of its manifestations, so much so that it is often difficult to foresee, even qualitatively, the results. In any case, the limitation of the study of the question to the case of rarified gases (or better still, extremely rarified) facilitates a great deal this study. For such reasons, and because in the case of the electronic emission in vacuum, the phenomena are more conspicuous, and having to draw from these practical applications, as those made in certain types of radio-telegraphic indicators, it is convenient to consider only those dispositions of apparatus elements which utilize the emission of electrons in a rarified gas.

The first researches made in this direction are those [237] of J. A. Fleming. Inserting in a circuit, forced to oscillate electrically with a frequency which may be high, a globe containing an incandescent filament and a plate, there results a passage of negative current from filament to plate every time the filament is charged negatively and the plate positively and not in the opposite case. A galvanometer or a telephone would thus indicate the passage of a continuous current. We thus obtain that which Fleming calls electric valve, since of the two directions of the electric current forming the electric oscillations, only one is of value. The addition of a constant e. m. f. in the circuit reinforces the phenomenon if it be such that the passage of electricity through the rarified gas takes place in the neighborhood of a sharp change in curvature in its characteristic curve.

DeForest, after Fleming, has tried to utilize the same phenomenon of the emission of negative electrons on the part of hot wires, obtaining apparatus (called *audions*) which are sometimes similar, at least in theory, to that of Fleming, but the form and the functioning of the last *audion* constructed by DeForest are very different from those of the *valve* of Fleming. (Rendiconti R. Accademia Dei Lincei, January 3, 1909). I had occasion, in a previous note, to express some ideas on the theory of the DeForest arrangement, even though DeForest himself has no explanation. I wish now to consider briefly such experiments which confirm my former mode of viewing the phenomenon.

The *audion*, in its latest design, is composed of a glass bulb with rarified air, containing three conducting bodies F, G, L; F is a metallic filament which becomes incandescent by means of a continuous current at low voltage (3 or 4 volts); G is a grid or metallic screen with rather large mesh; L is a metallic plate. Connecting F with L externally, and through an e. m. f. of about 30 volts, in such a manner that F be negative, electrons leave F and fall on L, after having traversed the grid G. This takes place regularly (and we can observe this fact by means of a galvanometer) since F and G have the same potential; if, on the other hand, F and G are connected to a circuit with persistent oscillations, the deflection of the galvanometer is diminished. Such an arrangement can, therefore, be utilized as an indicator, since this diminution, or the corresponding click or noise in the telephone, inserted instead of the galvanometer, is the indication of the arrival of an electromagnetic wave; the disappearance of this is indicated by the return to the first value of the galvanometer deviation, or by a second click in the telephone. By using the telephone alone, the above arrangement serves also to indicate insolated trains of oscillations damped in any manner.

To give myself an exact idea of the operation of the audion, I have constructed, as I will mention, different characteristic curves of the passage through such an apparatus of electricity transported by the electrons. [238] The audion made by me for such experiments has a tantalum filament 18 millimeters long, bent horseshoe shape, and traversed by a current of .5 ampere at a voltage 3.8 volts; thus the filament is brought to an almost white heat. The grid consists of parallel platinum wires of diameter .3 mm., distant 2 mm. from each other; the plate is square, 2 centimeters by 2 centimeters. The planes of the filament and the grid and of the plate are parallel, and the first distant from the second, and the second from the third about 4 mm. The grid G is in connection with one of the extremities of the filament; for example with the positive. Thus, its potential is not identical with that of all the points of the filament itself, since, as mentioned, the potential of the latter varies from zero to 3.8 volts. The results which I will now indicate refer to the connection made with the positive extremity; quantitatively, they would be as much different if they were made with the connection to the negative pole; but that would not have changed the general conclusion which I want to arrive at. The plate L is connected through a sensitive galvanometer to a regulable e. m. f. from zero to 50 volts with the same positive terminal of the filament F. The e. m. f. electrifies negatively the filament, and positively the plate, and



gives rise, therefore, to the passage of a current indicated by the galvanometer in consequence of the emission of negative electrons on the part of F. Varying the e. m. f. above mentioned, I began to construct the curve in the figure when the grid was in a neutral state. The curve is referred to two axes, one indicating the value of e. m. f. used and the other the deviation of the galvanometer. From such a curve, we see that the current of saturation is about two milli-aperes, with an e. m. f. minimum of about 30 volts. I construct two other curves obtained with the grid having a negative potential with respect to the positive terminal of the filament, and with a positive potential, respectively. The value of this potential is in each case 10 volts.

It is seen that the *negative* curve is depressed more than the neutral curve, and that the positive is still more depressed. Such depressions are a consequence of the electro-dynamic reaction between the grid and the elec-
[239] trons from the filament. If the grid is electrified positively, the electrons are in part directed by it, and reach in lesser number the plate; if negatively, they are still more impeded in trying to reach the plate, because they are repelled in part by the grid. In any case, the intensity of the current circulating in the galvanometer is diminished.

For these two curves also, the intensity of saturation, even though smaller, corresponds to an e. m. f.

minimum of about 30 volts, a value which is a little greater than that found by Fleming for his *valve*. This can be explained, in addition to considerations of other experiments, in the presence of the grid between the filament and the plate, which grid is entirely absent in the *valve*.

Examining the curve in the figure, we see that, for example, if we maintain a difference of potential constant to 30 volts between F and L (F negative), we obtain an intensity of 1.7 milli-amperes for the case of neutral grid, an intensity of 1.3 milli-amperes for the grid negative, and an intensity of 0.6 milli-amperes for the grid positive plate. Connecting between F and G and the alternating E. M. F., a maximum value of 10 volts, I found an intensity of 1.2 milli-amperes. Such a value represents a sort of mean value, depending either on the instantaneous values of the sinsusoidal e. m. f. or on the dissymetrical action of the charges positive and negative.

The electrification of the grid with respect to the filament produces, therefore, in any case, a diminution of the intensity of the current between the filament and plate; and this is true, even when such electrification comes from an alternating electromagnetic action of high frequency, as in the case of radio-telegraphy.

The above considerations, and the experimental results noted, give data for the explanation of the operation of the audion as a receiver in radio-telegraphy. It does not seem to me that we can speak of a true selection of waves, the negative from the positive, as Fleming would have it, and as in the *valve* of Fleming really takes place. In the audion, both charges, positive and negative, generated by the waves, act to depress the characteristic curve of the current of electrons falling on the positive plate, whereas in the valve, only the half-waves, which produce negative electrification of the filament, have effect.

Such explanation of the functioning of the *audion* leads us to the conclusion that the energy necessary to the formation of signals in a galvanometer or telephone is not, at least exclusively, a transformation of the energy in the radio-telegraphy wave. Rather we should consider that these signals are formed, in great part, at the expense of the energy furnished by the local battery. This fact is particularly interesting inasmuch as in certain cases, the energy taken from the battery can be superior to that received by the receiving antenna. It is very useful, therefore, following this general lead, to push recent researches enabling us in this manner to arrive at the construction of indicators of superior sensitivity to those heretofore known.

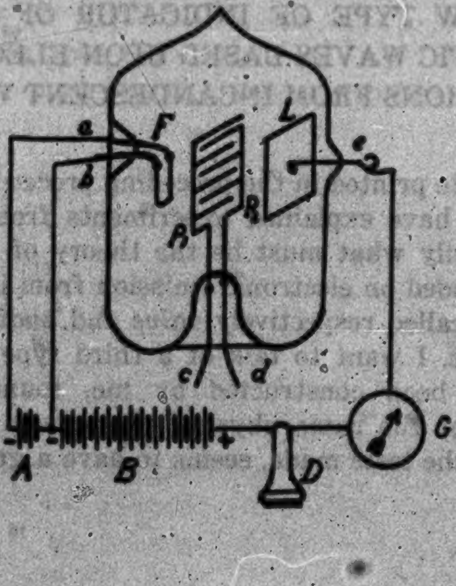
ON A NEW TYPE OF INDICATOR OF ELECTROMAGNETIC WAVES BASED UPON ELECTRONIC EMISSIONS FROM INCANDESCENT WIRES.

[274]

In a note printed in the preceding proceedings of this academy, I have explained experiments from which we deduce readily what must be the theory of the two detectors founded on electronic emission from incandescent wires, and called respectively *valve* and *audion*. In this [275] note, I want to talk of a third type of detector which has been constructed by me, founded on the utilization of the same physical phenomena. This new type, from the tests made, seems to have a greater sensitivity than that of the audion, which heretofore was considered the most sensitive radio-telegraphic indicator. It can be called "Electronic Deviator", and is based on the concept of producing displacements of deflection of the electronic currents coming from an incandescent filament, and falling on a cold plate by means of electrifications, either positive or negative, produced by the arrival of the electromagnetic wave. To such displacements correspond diminutions in the local current, which give rise to the formation of signals, for example, in a telephone. In order that the arrangement, which I will describe, be of exquisite sensitivity, the displacements produced by this arrangement are *normal to the direction of the electronic emission.* It consists of the following:

The glass bulb of about 3 centimeters in diameter (see figure), and *in which the vacuum has been made*



as high as possible, contains four conducting elements; F is a filament, preferably metallic, which can be heated by means of a current from battery A, through the wires *a* and *b;* and *p1* and *p2* are two metallic combs contained in the same plane in which the wires alternate without touching. The combs communicate respectively with the wires *c* and *d;* L is a metallic plate, communicating with the wires *e*. The planes of the filament, of the combs, and of the plate are parallel, and distant, one from the other, a few millimeters. A battery B of about 30 volts electrifies negatively the filament and positively the plate L. In this circuit are comprised a galvanometer G and a telephone D. Under these conditions, if the filament is brought to an almost white heat, there circulates a continuous current which can be, depending on the form and dimensions of the apparatus, about half a milli-ampere. The negative electrons which from the [276] filament go to the plate, and to which is due such current, traverse the space between the combs *p1* and *p2* and in part are retained by the latter. The form, the distance from the filament to the plate, and the dimensions of the combs have been studied in such a manner that diminution of the electronic current, registered by the galvanometer, by the presence of the combs themselves, is about 10%. That such takes place, the potentials of the combs must be identical, and that they do not differ very much from the mean potential of the incandescent filament F. If, however, we create a difference of potential, even small, between *p1* and *p2*, the intensity of the current which is observed in the galvanometer diminishes immediately. This comes from the fact that a part of the negative electrons, being repelled by the negative comb and attracted by the positive comb, fall on the latter rather than on the plate L. The arrangement is so sensitive that about 10 volts is necessary to bring almost completely the current register in condition of repose by the galvanometer, to induce variations in the current corresponding to the noises in the telephone.

If now, instead of the static charges on the combs, we have alternating charges, the arrival of negative electrons on the plate varies the alternations of the charges themselves. The galvanometer, because of the inertia of its movements, finally registers a mean deviation inferior to that of maximum at repose; and the telephone, within the limits of its functionability, gives a tone if the frequency of the alternation is of acoustic character, and is silent if we have rapid electrical oscillations, persistent and constant; or registers with noise or sound the variations or the modulations of the oscillations themselves. Thus, the described arrangement can very usefully be used in radio-telegraphy or radio-telephony. For this purpose, it is merely necessary to connect the terminals *c* and *d* with two points in the receiving circuit between which there exists a difference of oscillating potential; for example, with the extremities of a condenser forming part of such a circuit.

The *deviator*, being sensitive to the differences of potential and not to the oscillating currents, must be applied in a place where such differences are greatest. It is, therefore, advantageous to construct an oscillating circuit resonating with the antenna, which latter is in resonance with the arriving waves, having great self-induction, and very little capacity. This circuit is connected directly with the *deviator*. Practically the capacity can also be suppressed, the capacity of the combs and that of the oscillating bobbin being sufficient to obtain a resonance, the oscillating bobbin in the case, possessing relatively very high self-induction.

As far as concerns the reliability of this apparatus, I can state that the *deviator* has given very good results. The only thing we must avoid is the excessive incandescence of the wire: for, if on the one hand it gives rise to a notable increase in the sensitivity of the apparatus, on the other hand, besides reducing the life of the apparatus itself, renders necessary continuous variations in the local battery e. m. f. in order to obtain the [277] maximum effective reception. Such variations result from two causes, on the one hand from the changing of the state of rarification of the bulb, depending upon the emission, or at times, the absorption of gas on the part of the incandescent filament; on the other hand that which is more grave, on the deposit of metallic oxides, coming from the volitization of the filament. This deposit forms gradually on the plate L and in time makes the surface nonconductive. This, I have been able to determine from plates taken from *deviators* that were of no further use. These deviators, whereas at first they used to work well with 20 to 25 volts, had to be used with more than 100 volts in order to give rise to sufficient passage of negative electricity from the filament to the plate. In this respect, it is preferred to adopt a carbon filament rather than tantalum metals which usually are used. Carbon gives rise to deposits which are always conductors, but has the inconvenience of requiring greater energy in comparison with metallic filaments for radiating the same quantity of negative electricity. From what I have explained, and keeping in mind what I said in the previous note, there results that, whereas the *valve* acts only onto the action of the negative waves, the *audion* is sensitive to both half-waves, but with preference to the negative; and the *deviator* is sensitive equally to the half-waves of both sides.

As to the practical results obtained, I can briefly give the following: A *deviator* records the signals received from an antenna 24 meters high of the Institute Superiore dei Delegrafi in Roma. It is capable of registering with great intensity those of the station of the R. Marina Italiano, which is nearer, and very well those of almost all the others, and from the ships in the surrounding waters of our peninsular. The Victoria Station in Sicily (distant 580 kilometers), when working in good conditions, gives signals to the *deviator* which can be heard even if the telephone is detached 5 centimeters from the ear. As mentioned at the beginning, the *deviator* can act with alternating charges of any frequency. It, therefore, besides being capable of use as *radio-telegraphic receiver*, can evidently act as a *telephone repeater*. It is only necessary for this purpose to use an induction coil, the secondary of which has a large number of turns, and to unite the extremities of such a secondary with the two combs of the *deviator*. The differences of oscillating potential with the acoustic frequency, and induced in the primary of the coil, create charges which give rise to pulsations of current traversing the circuit of the battery B, sufficient to reproduce very clearly the sounds or the voice transmitted in the telephone D. In order to be able to call the electronic *deviator* also by the term *telephonic relay*, we must have the energy received by the telephone D greater than the one admitted into the telephonic induction coil. This, in truth, does not seem to take place in the case of apparatus constructed by me with form and dimensions proper for the needs of radio-telegraphy; but I reserve, therefore, for a future date, the explanation of other experiments and instructions on this subject.

An X-Ray Tube of an Optional and Instantaneously Attainable Degree of Hardness Independent of Vacuum

By Dr. J. E. Lilienfeld and Dr. W. J. Rosenthal.

(Addendum Table XVII.)

Part I.

DESCRIPTION OF THE X-RAY TUBE AND ITS PHYSICAL PROPERTIES.

By J. E. Lilienfeld.

1. *Fundamental Facts and Description.*

The illustrated tube differs from the usual X-ray tubes by the feature in the first place, that it is as far evacuated, the metal in it is as completely denuded of the occluded gases in it, as possible. It offers therefore a resistance to the passage of the current between the ordinary aluminum cathode and the anode which cannot be overcome by the voltage of an ordinary induction coil or rectifier. In the known tubes the conductivity required for the passage of the current is given by the greater or lesser gas density in the tube. In the new construction before us, however, this conductivity is independent of the density of the gases contained as residues in the tube and produced in any quantity through a particular process. This procedure is technically feasible through the fact, that between a sufficiently highly heated cathode of heavy fusible and hard-sublimating metal on the one hand, and an anode of the usual kind there can be produced a discharge in the vacuum with low tension. The incandescent cathode may be coated thereby with earthly potassium oxides according to Wehnelt.

I found that the required voltage for the production of a certain current strength from an incandescent cathode, which at first, diminishes, when the tube is evacuated, then again begins to increase, as the gas attenuation is carried, beyond a certain limit. This tension does not then increase with diminishing pressure, but remains stationary at a certain limit, i. e., if it reached this limit, and the tube is further freed of gas, the tension no longer changed with diminishing pressure. In the X-ray tube to be described, this tension is of a magnitude which is just exceeded by the usual tension of a city system. It may be seen from the actual connection given that accordingly a discharge between an incandescent cathode and an anode with a relatively low tension current a discharge may be produced even in the highest vacuum. At all events the tension drop in the path of discharge is so great because of the highly developed vacuum that the tube, for instance, cannot be used as a valve for the current source so that by sacrificing a small part of the energy of the desired phase, the balance of this energy is used up outside of the tube, with simultaneous cutting out of the opposite phase.

The incandescent cathode is marked 3 in the figure. Wires 3′ and 3″ conduct the current necessary for its heating. The energy consumption of this heating circuit corresponds to that of an incandescent lamp of medium intensity. 4 is the cylindrical anode. The discharge taking place between 3 and 4, supplied by the city network or another suitable current source, will hereinafter be called the primary discharge.

Now, I found—and this is the fundamental fact for the construction—that this primary discharge develops a conductivity in the interior of the tube in the highest vacuum, hence in a vacuum which no slides and cementations are used in order to insure stuffing up, and which is forced as far as possible by all available means. As we shall show further down, this is something that we may denote from the general standpoint as surprising considering the strict bipolar character of this phenomenon. All the more surprising when the bipolar character is maintained even then, when the conditions of the experiment are so chosen that the lighting up of the spectrum of the last gas residues are as good as entirely absent (cf. par. 8, a).

This is the conductivity which, as already indicated, takes the place in the new construction of the conductivity created by the gas filling in the usual tubes. It has a feature specially predestining it for this purpose: it arises and vanishes, increases and wanes instantaneously with the primary current. If therefore the negative pole of the magneto is applied to a cathode of the usual form 1, while the positive one is connected with 4, there will occur a high-tension discharge based on the conductivity produced by the primary current. The energy of the cathode rays of this discharge is caught up with anticathode 4 connected with 3, and partly transformed into X-rays on its mirror. The greater the primary current, the greater the conductivity, the smaller therefore, the tension required for the production of the current, the slower the cathode ray to be applied here, the softer the X-ray thus produced, and vice-versa. But as the conductivity instantaneously changes with the primary current, thus accordingly the resulting X-ray radiation becomes instantaneously softer with the increasing primary current, harder with diminishing current, between limits taken entirely at will. We are therefore practically in a position to give to the discharge instantaneously any degree of hardness we choose by simply displacing a contact on the resistance regulating the primary current.

Numerical data, as well as the description of the extreme by simple manipulation of the tube are contained in the second part of the work before us. We should emphasize more especially that these data are applicable for the case where the primary discharge is produced by a direct current. If an alternating current is used for this purpose, very divergent conditions arise, the details of which will be given below.

2. *Duration, Intensity, Distinctness.*

In this first part of the work, let us indicate at first the following from the technical standpoint.

(a) Pulverizations do not at all occur in the tube, and other injurious effects of the current at closing are also eliminated. As the density of the gas is also of no importance, thus the duration of the tube is mainly determined by the duration of the incandescent electrode 3. And this is a very long one; it may be figured in hundreds of hours of service and will be comparable in duration with the duration of an incandescent lamp according to its size.

(b) There are as yet no available data regarding the intensity of the radiation under equal charges in tubes of the ordinary make. Judging from all appearances, however, the anticathode heats up conspicuously little under considerable intensities of the X-rays. If we consider that, as a result of the extreme evacuation of the tube the calorification of the anticathode is restricted by the impinging negative ions, it may be expected that the saving in the rays is a very favorable one. For such negative ions, arising especially under great gas densities, hence in soft tubes, bombarded by the cathode to the anticathode, calorify and destroy only the mirror of the latter (similarly to the pulverization through impinging canal rays) without such energy contributing in the slightest possible degree to the increase of the X-rays. A proof of this may be had in the fact that, as is generally known, the mirror in extremely soft tubes becomes incandescent even under a relatively small charge and corrodes while these conditions are very much more favorable in the case of very highly exhausted tubes. In fact the differences are so marked, that they are from every indication of another order of magnitude than those which might be expected on the basis of a procentual output of X-ray energy in the case of speedy cathode rays.

(c) As the development of disturbing wall charges is prevented in the entire space through the good conductivity conditioned by the primary discharge, it is to be expected that the cathode rays are not electrostatically deflected from their normal course. But the constancy of their focus hangs together with the unruffled path of the cathode rays, hence also the distinctness of the image. In fact it will be recognized from the images discussed in the second part that the tube satisfies wide expectations in this connection.

3. General Considerations.

It is to be mentioned from the general physical standpoint:

(a) The construction here described owes its being to the considerable studies I have carried on in connection with discharges in extreme vacua. The latest report in this connection was published in vol. 43 of the Berichte der math.-physik. Klasse of the Kgl. Gesellschaft der Wissenschaften, Leipsic (1911, pp. 534-539). This publication brings a new construction for the fact that, in case the current density of the discharge in extreme vacua exceeds a perhaps very small minimum value, there is an equivalent number of positive charges to offset the negative electrons which serve for the current transportation. In fact the laws applicable to the conduction of electricity are independent of the magnitude of the vacuum, provided that a certain limiting value of gas density is not exceeded.

This is a result, which contracts the generally expected behavior of things according to popular ideas, as we have already passingly mentioned in par. 1, in connection with the absence of the spectral illumination of the last gas residues. For the positive charge is bound to the atom and the molecule in the shape of an ion. Now, if the matter is considerably removed from space by exclusing slides, cementations and mercury vapors and using the best available means for the production of the vacuum, it is to be expected that the number of positive charge carriers, hence also the spacial density of these charges is constantly becoming smaller. And it is to be foreseen that there will finally be obtained a vacuum in which the transportation of electricity is mediated solely by the negative electrons emanating from the incandescent cathode. In reality the opposite is the case, as a result of the above determination.

It was of value for the continuation of my experiments, to obtain a technical possibility for the production of cathode rays of optional speeds in high vacuum. I made an apparatus for this purpose which could be so easily handled that I could not refuse myself the use of these cathode rays for the production of X-rays. Thus arose the technically very thoroughly developed type of X-ray tube we have described.

(b) The considerations which led up to my construction, are based on the knowledge of the laws indicated in (a.). The high vacuum crossed by positive and negative charges in the current path is manifestly an electric conductor. And in fact a conductor, the excellence of which below a certain limiting value of gas density is given independently of the gas density, solely through the density of the electric current. It was therefore to be supposed that, in case a discharge is produced between two electrodes in the high vacuum created by this current, the tension required to drive a certain current strength through between these electrodes, this will be given by the density of the current conditioning the conductivity, which we have called the primary current. The experiment confirmed not this supposition alone; it could be observed beyond it, that between the secondary electrodes, as it appears, an independent discharge is used. Especially did the secondary cathode send out cathode rays which appeared to have emanated from its surface through the bombardment of the carriers of positive charges in an extreme high vacuum. This construction of the processes, which is at first given only according to the general appearance of the discharge, requires at this time a substantiating proof to be obtained from exhaustive experiments. But it is supported by the fact that experience showed the tube construction here illustrated as by far the most favorable, where the primary discharge takes place at the first possible distance from the secondary cathode; hence outside of the dark space surrounding this cathode, if I may transfer the current appelation for the ordinary independent gas discharges to the present deviating conditions.

(c) There may be wanting in the above discussion perhaps a comprehensive listing of the fundamental physical measurements required for the use of X-ray tubes. From the just indicated development, however, it will be deduced that the construction was originally designed, solely as a means of investigating a field of phenomena; that, furthermore, so far as we can forsee, there will be obtained from this coming investigation a more fundamental result for the understanding of the processes in the tube, than from an empirical combination of various experiments on an apparatus, in which relatively complicated processes take place which have not yet been sufficiently investigated according to the principle underlying them. And it will therefore be found justified if I bring before the public a technically useful tube with the hope to leave the systematic measurements, partly to engineering, partly, however, to my further investigations to be made in the near future.

The principle of the tube was laid before the Biological and Medical Society at Leipsic, on December

18, 1911, by X-ray photographs of the hand and the chest. The present publication is the first in print.

Part II

Practical Application of the X-Ray Tube

By DR. W. J. ROSENTHAL.

Assistant on the Surgical-Polyclinic Institute of the Leipzic University.

The chief shortcoming of all hitherto constructed X-ray tubes is that its degree of hardness depend on its gas contents. The result of this is, in the first place, that a new tube quickly becomes soft under the influence of the heating. For its glass walls and its electrodes will give off some gas, which they contain in the "latent" state.

As the tube is longer in service, the gas contents of the tube are more and more used up. Careful manipulation and some kind of regeneration devices might perhaps retard this shortcoming. At length, however, every tube becomes so hard after new exhaustion, that it is no longer to be used. There is as yet no X-ray tube, the degree of hardness of which may be varied as long as desired or which can be kept constant at will.

A further disadvantage of the prior-art tube is for one the metal pulverization in its interior, whereby the hardening of the tube is accelerated, on the other hand, however, the calorification of the anticathode, occasioned by long exposure and stronger charging, which endangers the tube.

Now, as shown by his previous exposition, Dr. Lilienfeld has constructed an X-ray tube, which has the advantage, that it possesses a degree of hardness that may be varied as quickly as desired. This variable degree of hardness of the tube is independent of its vacuum.

He has rather succeeded to regulate the discharge tension between the cathode and the anode in the tube by means of an independent primary discharge circuit, and thus to change at will the degree of hardness.

As proof that the very greatly exhausted tube without the conductivity current is not permeable for the high tension currents was the experiment of producing discharges in the tube with fully switched Grissen-transformer. The tube did not function here at all, while the discharge, e. g. indicated the presence of tension quite distinctly in a Guodelach-valve tube or in the parallel spark gap.

I will give a short report of the practical experiments which were performed with the new tube.

The application of the tube is very simple. Before every X-ray picture or photograph the heating current of the incandescent cathode and at the same time the primary discharge current, which makes possible the discharge between the cathode and anticathode, regulating same, is switched on by means of a cock. (The description of the small additional electrotechnic appliance, which is required for operating the tube with a set of instruments that may chance to be available, will be given, and also the most convenient method of operation established on the basis of a considerable amount of practical experience). Both currents may be left in service as long as desired, without any injury to the tube. The photographic plate in the usual individual service is not in any way attacked by the light of this source which emits only ordinary light rays.

The heat current remains constant. It corresponds to the one in a medium-strong incandescent lamp, according to the number of watts used up.

The primary current sent through the tube, which varies the hardness of the tube as desired during the photography, is changed by 50 to 180 milliamperes. If the current in the primary discharge circuit is raised above 180 milliamperes, the tube sends out such soft rays that they are of no use for photography. With soft arrangement, that is about 150 milliamperes, the outlines of the dark phalanges may at once be recognized on the X-rayed hand.

If we reduce the conductivity current to 100-80 milliamperes the tube becomes harder. The bones in the outstretched hand appear more distinct, and take on the typical light grey color by further diminution of the primary current to 50 milliamperes, as given by hard tubes on the barium-platinum cyanide screen. In X-raying the thorax, the various ray hardnesses can be recognized characteristically on the more or less clear appearance of the mediastinal organ against the bony chest. The degree of hardness of the tube used in the X-ray photographs varies between 5-12 wehnelt, measured with the Wehnelt cryptometer.

The heat developed in the anticathode is a comparatively small one even after a longer exposure (30 minutes without interruption with the fully switched Grisson transformer). A strong copper rod, conductively connected with the cathode may then be touched with the hand without any danger. The calorification of the glass as compared with the anticathode is naturally smaller than with the usual tube for every possibility is eliminated that the current at closing should produce an injurious and metal destroying effect.

Of the X-ray photographs, which were taken after previous regulation of the tube to a certain degree of hardness, I will reproduce two sets of three photographs each. (Compare the pictures.) I may mention that all photographs were taken without strengthening screen (folium). Besides the three degrees of hardness reproduced there exist naturally transmissions, as well as extremely hard, super-illuminated plates.

Group 1.

Three hand photographs, which were taken in immediate succession, after previous regulation of the hardness of the rays (extremely soft to hard) under the same exposure period. Pictures 1-3.

Object	Illumination Period	Distance of Tubes	Degree of Hardness Wehnelt Scale	Strength of Conductivity Current
Normal left hand of an 18 year old				
Right hand of the same man - - - -				
Fract. metacarp. III and V - - - - -				
The same object as 2				

ad. 1. The dark phalanges may just be distinguished from the soft parts, while the middle hand bones do not at all rise into view from their surroundings. There is no bone detail sketch.

ad. 2. On the end phalanges the structure of the bone becomes already somewhat prominent. At any rate, the bones are clearly distinguished from the soft parts, but all details are missing.

ad. 3. Distinct demarkation of the bony structure. About the phalanges the soft parts in lighter tones. The prominent fracture lines are noticeable. (Fract. metacarpi III and V.)

Series 2.

Three hand drawings, which were also taken in immediate succession after previous regulation of the radiation hardness (hard to extremely soft): Photographs 4-6.

Object	Illumination Period	Distance of Tubes	Degree of Hardness Wehnelt Scale	Strength of Conductivity Current
Normal left hand of a 30 year old man				
Ditto				
Ditto				

ad. 4. Very prominent bony structure of a normal hand. Great variation in the tones and ample details.

ad. 5. The same hand. Details are yet hardly noticeable on the dark colored bones. The soft parts also in dark color tones.

ad. 6. The same hand. The phalanges shown as deep black shadows. In the middle hand almost no differentiation of the bones from the soft parts.

As shown from the picture, it is possible to make X-ray pictures of full distinctness with the tube in any rapid succession by simply changing the conductivity current, and also such in which the bone just appears differentiated from the soft parts. And in fact the tube passes through the degree of hardness from extreme softness to extreme hardness with the same speed, as vice-versa. But it may also be kept at a given degree of hardness for any length of time unchanged. The main condition therefore at the hardness of the rays is solely the strength of the conductivity current, which may be changed or kept constant at will, and not by the minimal gas quantity which is still present in it.

In order to prove that photographs of heavier objects may also be made with the tube, I desire to reproduce also a shoulder and thorax photographs (Photograph 7 and 8), which are made with another tube specimen.

Object	Illumination Period	Distance of Tubes	Degree of Hardness Wehnelt Scale	Strength of Conductivity Current
Normal left shoulder of a 15 year old boy - - - -				
Normal thorax of the same individual - - -				

No. 7 gives a very prominent picture of the normal shoulder, while 8 reproduces the thorax full of contrasts. The fact that the thorax plate shows easily vanishing outlines of the ribs is explicable by the comparative duration of the illumination (40). But this does not depend on the tube, which certainly supports charges of short duration, but on our instruments. Photographs and readings were taken at first with a combined improvised apparatus in the Leipzic Physical Institut. The Grissonator, which delivered the tension did not permit itself to be switched on suddenly with a full charge, as it is necessary for short readings of thicker objects, for the fuses burnt out. We had therefore to leave the half of the series resistance in the primary current, circuit, and to illuminate for a correspondingly longer time. At this time the accessory instruments (cf. footnote p. 260), which may be obtained at a small cost, is connected in the proper manner with the X-ray apparatus of the Chir. Universitaets-Poliklinik, that we shall soon be in a position to report about readings with short illumination with the new tube.

One more thing may be mentioned about X-ray readings at longer periods. As we are able to pass through the entire gamut of hardness during the reading, even when it last a short time, it may be imagined that we obtain with them pictures rich in contrasts, by superposition, as it were, of a hard and soft reading from the same focus.

On the other hand, again, there may be precisely arranged before the reading on the fluorescense screen the degree of ray-hardness required for the exact object, hence as it were the Roentgenographic optimum. One may be sure that the respective readings occur by means of rays of the required hardness.

As to the application of the tube for therapeutical purposes, I believe I can assume that it is very greatly useful for this purpose.

Firstly because of the great duration, which in practice is limited only by the destruction of the metal of its incandescent cathode. Secondly, because it may be kept constant at every desired degree of hardness, as already stated.

The same tube will therefore allow the production with rapidity of the hardness required for irradiations, which tube is also to be used for readings, thus obtaining the desired depth effect. Likewise, when specially soft, biochemically strongly effective rays are used, for the treatment of irradiation of superficial, malignant tumors, the tube can be held at the same softness for the period of all irradiations.

The advantages, which the new X-ray tube has in comparison with those hitherto used, are therefore to be summarized as follows:

1. The tube receives a degree of hardness independent of its vacuum.

2. This degree of hardness may be changed at will and as rapidly as possible with the aid of a primary current circuit.

3. In this way, the tube may be regulated for any desired degree of ray hardness before every X-ray read-

ing. Likewise the most various degrees of hardness may be applied in the same radioscopy.

4. The durability of the tube seems to be especially good, even under longer exposure and higher load. Its duration will be as far as we can forsee, the same as that of a metal filament lamp.

5. The heating of the anticathode as well as that of the glass-wall is a comparatively slight one.

6. The metal pulverizations do not seem to take place in the interior of the tube.

We will report further on the practical application of the new tube.

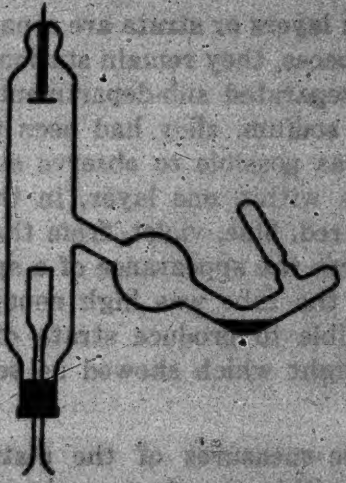
ABOUT THE DISTRIBUTION OF LIGHT DURING THE STRATIFIED DISCHARGE IN VAPORS OF ALKALI METALS

By JACOB KUNZ and JAKOB G. KEMP.

While studying the photoelectric properties of the alkali metals, it has been observed that a plainly noticeable separation of the colors of the light during the stratified discharge occurred in the electric discharge produced by the vapors of these metals. It could be noted that towards the cathode a blue light was produced and that towards the anode, however, a reddish and violet light of potassium vapors was noted. According to the radiation theory of Planck, one should have expected that nearer the cathode that light would occur in which the light quantities have the least value, thus red and yellow light. In fact, the energy quantity, which is produced by a radiating resonator, increases in proportion with the frequency and, on the other hand, the kinetic energy of the electrons leaving the cathode ought to increase depending upon the distance from the cathode. If now the energy of the ionizing and light producing electrons increases, it should be expected that the values of the emitted light quantities increase according to the various distances from the cathode. This, however, is not always necessarily the case, as, according to investigations made by J. J. Thomson, the field direction in the stratified discharge may be reversed. It is therefore, only possible to decide by way of quantitative measurements whether there is a contradiction as to the radiation theory of Planck. Some quantitative experiments have been made which were supposed to determine the conditions of the separation of the light rays in the radiating strata.

The tube to be employed had the shape as per accompanied figure. A Wehnelt calcium oxide electrode has been used as cathode, while a small aluminum disk constituted the anode. The distance between the two electrodes was about 12 cm., the diameter of the tube amounted to 2,3 cm. Potassium and sodium was placed and vaporized in the lateral extending portion of the tube. A complete vacuum was produced so that Roentgen rays were created, without heating the Wehnelt cathode. As soon, however, as the calcium oxide electrode had been sufficiently heated, then there appeared the blue rays of electrons which spread from the cathode to the anode, however, without producing any other light.



It seemed to be difficult, even impossible, to produce a stratified discharge when using potassium exclusively. However, as soon as a small quantity of hydrocarbon gas had been introduced, and the tube was slightly heated, the separation of the various kinds of lights could be plainly noticed. The lower part of the strata appeared well blue, and separated from the next violet layer by mathematically determined margins. The hydrocarbon gas was plainly obsorbed by the alkali metals.

The direct current potential difference between the electrodes amounted to 450 volt maximum, the current increased sometimes to 0.02 amp. It is mostly necessary to start the discharge by means of an induction apparatus.

The various layers or strata are separated from each other by dark spaces, they remain stationary, and consist of thoroughly separated sub-departments. In case the fluid potassium sodium, alloy had been used, instead of potassium, it was possible to observe even four plainly separated strips within one layer, in the following sequence; yellow, red, blue, violet, from the cathode to the anode; it produces the appearance of a spectrum. If the temperature of the tube was high enough, then it was sometimes possible to produce strata of almost purely yellow sodium light which showed no separation of the colors.

Quantitative measures of the distribution of the electric energy within the strata or layers, accompanied by a spectroscopic test, and of the influence of helium and hydrogen gas will render new lights about the ample and beautiful phenomena.

VACUA

BY W. R. WHITNEY

The purpose of this article is to publish a few observations made in the research laboratory on some phenomena in vacua, as they may possibly be of interest to others who are working in the field of evacuated apparatus.

The subject has a double interest because at first glance it seems difficult to see how there can be much ground for study, or material and phenomena for useful investigation, in such an apparently confined volume of nothingness as the vacuum of an incandescent lamp. The many actual developments from this lack of material are interesting, and there is the added interest due to the fact that there are to be found in these lamps examples of many of the phenomena of gaseous ions which are receiving so much study in our day.

It has long been known that the life of an incandescent lamp is greatly influenced by the quality of its vacuum. In general, one may say that the better the vacuum, at least up to a certain point and until recently, the longer the life of the lamp. In the early days of lamp making, many schemes were devised to improve the vacua. This was then all the more necessary, as the mechanical methods of lamp-exhausting were very much inferior to present ones. The harmful effects of oxygen and water vapor, both of which reacted upon the filaments, were well known and many ways were devised for removing them.

What seems to be an especially interesting method of supplementing the vacuum pumps was the method of Malignani. This process, in its most perfect form, consisted in distilling into the bulb a small amount of some such substance as arsenic, sulphur, iodine, or phosphorus. At the instant when one of these vapors was introduced, he passed a high current through the filament, the lamp being closed from the pump. This has long been the common commercial process for lamps which are to operate on voltages above 50, and many millions of lamps have been exhausted by its aid.

In case of incandescent lamps where the voltage is above 50 for a fair brilliancy of filament, a blue discharge passes through the bulb and this blue quickly disappears when such vapors are introduced. The blue discharge seemed to be necessary for any considerable improvement of the vacuum, due to such vapors as phosphorus, and this led to the assumption that the gases still left in the lamp by the pump were removed quickly during the blue glow and probably by the vapors which were at the same time being deposited on the glass. Although the facts were pretty well known, we performed experiments to study the phenomena. It was found that when the vacuum was measured by a McLeod gage, the sudden marked improvement of vacuum was easily proven. For example, in experiments carried on by Mr. Willey, of the laboratory, when the pump had produced a vacuum of 0.030 mm. mercury and the cock leading to it was closed, a trace of phosphorus was distilled into the bulb while the filament was very hot and a blue glow had appeared; then about as quickly as the gage could be read the pressure had fallen to 0.002 or 0.001 mm.

That this improvement of vacuum is quite commonly produced when vapors of any kind are caused to condense in the space is not new. It even takes place markedly when the filament is first heated to very high temperature without added vapor, and a *blue glow* also passes through the lamp at the time. In improving the vacuum this latter way, however, it is known that the filament is injured and apparently a part of its material has been vaporized. This process soon causes blackening of the bulb by carbon.

This vaporization of phosphorus into the lamp at the moment when the pump has done its work, has long been the commercial method of finishing the exhaustion of incandescent lamps. The fact that even the carbon alone tended to the same end, though at the expense of the filament, being recognized, it became of interest to get a clearer view of this phenomenon.

In other words, if an incandescent lamp was burned while connected to a McLeod gage and the vacuum became poorer, the changes of vacuum might be measured by the gage from timto time. If, on the other hand, the vacuum improved so that the pressure tended to become less than the vapor pressure of mercury at the temperature of the gage, then the gage would not only not measure it, but the mercury vapor might even have affected the life of the lamp. When experiments were made to determine the effect of the vapor of mercury at the low pressures corresponding to a micron, which is the vapor pressure of mercury at 15 deg. cent., very peculiar results were obtained and the lamps showed very early blackening. It looked as though even the presence of this constant mercury pressure was fatal to the lamp. Therefore the discovery of a more practical vacuum gage was desirable.

Without committing ourselves to a theory, we can describe one or two interesting experiments with mercury vapor. It was first discovered that an incandescent lamp grew black very quickly when attached to a mercury column which served as a gage to indicate evolution of gas. No such combination could be made to last over a few hours. The lamp blackened just as though it was in an imperfect vacuum. It is hard to see how the mercury can have any chemical effect upon the filament as oxygen or water have, and the effect is common to carbon and tungsten lamps. Many lamps were then made which were exhausted as perfect lamps are exhausted, except that a small quantity of mercury was left in the bulb. It was assumed that this would not interfere with the removal of air and moisture and might even assist by the washing effect of the mercury vapor, mechanically removing air. Lamps were also made in which a large quantity of mercury was placed, the lamp put into an oven above the boiling point of mercury and the air washed out by the distilling mercury, no pump being used. When the mercury was nearly all removed the bulb was sealed. This method, if no visible mercury is left in the bulb, is capable of giving good lamps, but where a visible drop of mercury was present the lamp would show a persistent blue glow and rapidly blacken, even below its normal voltage. In some cases it would arc between the leads, exactly as in the case of poorly exhausted lamps.

Lamps were also made to which were attached tubes which carried small globules of mercury. When these side tubes were short and straight, such as one or two inches, and the lamp was exhausted as well as possible on the pump, the blackening of the bulb started at once when the entire glass was at ordinary temperature. If the side tube with its mercury was then submerged in different cooling mixtures, the length of time for a given blackening was increased. For example, at room temperature the lamp would be blackened so as to correspond to 80 per cent of its original candlepower, in a few minutes. When the side tube containing the mercury was at 0 deg. cent. this time became two or three hours; and when cooled in a freezing mixture at 20 deg. cent. the life to 80 per cent was over 75 hours. Such differences were also noted when the pressure of mercury vapor was controlled by using different cadmium amalgams, the amalgams higher in mercury corresponding to the shorter lamp life.

It was interesting to note also that by lengthening the side tube containing the mercury, the rate of this deposition of filament material in the bulb was decreased.

In a set of experiments at ordinary temperatures the length of the side tube was increased and it was wound as a spiral. This reduced the rate at which the mercury could reach the bulb proper. In this case, instead of there being a continuous faint blue glow, as there is when the mercury is in a short side tube, the blue glow appeared and disappeared continuously and regularly. It looked as though there was a certain pressure of the vapor necessary before the blue discharge could occur and that when this was reached, the sudden discharge produced the blue and cleared the vacuum to a much lower pressure. Then mercury vapor distilled anew from the long side tube until again the necessary pressure was reached, when the process of clean-up repeated itself.

If the lamp bulb was kept very hot, the blackening was reduced and even done away with altogether, as though the deposition of the mercury vapor upon the glass by the discharge signalized by the blue glow, could not take place. If, however, water vapor was present, even in very small amount, the blackening would take place very rapidly, even in the absence of mercury. In other words, most ordinarily exhausted lamps will blacken relatively quickly if allowed to burn in a heated oven. In general, the hotter the oven the more rapid the blackening, but this process is largely, if not entirely, due to imperfect exhaustion. All glass contains water which can be removed but slowly, even at relatively high temperatures. It has even been found that indefinite heating of a lamp connected to the vacuum pump is not capable of removal of all of this water. If exhaustion be carried on for a very long time at room temperature, then merely raising the temperature will cause liberation of more gas, and after heating and exhausting to an equilibrium condition at say 200 deg. cent. more water will be produced on heating to 300 deg. cent. and still more at 400 deg. For this reason it is customary to exhaust at as high a temperature as possible. At 400 deg. cent. the ordinary glass has reached its limit, owing to the proximity of the softening point. For this reason we have had to exhaust the oven in which the lamps were being exhausted, and thus remove the atmospheric pressure, in order to study the water evolution at higher temperatures.

For a long time it was impossible to follow the change of vacuum in a lamp, because the pressure could very evidently not be reduced below the vapor pressure of the mercury of the McLeod gage attached to the lamp. It has long been known, also, that the current passed through the space of the bulb to a considerable extent, and that this varied with the degree of vacuum, etc. A very complete discussion and description of experiments on this so-called Edison effect are given by Professor Fleming, in Vol. 42 of the *Philosophical Magazine*. In general, the conclusions are that in the vacuum of an incandescent lamp a current can flow across the space from the negative and of the filament to any conductor in the bulb, if this be so located that particles passing in straight line from the negative leg may come into contact with this conductor. This latter was usually a small platinum plate, and to it, as anode, a continuous current flowed from the negative half, or end of the filament, except when it was intermittently shielded from direct emanations. The current, often of several milliamperes, was measured by a galvanometer connected between the metal plate and the positive terminal of the lamp. It is known that the materials of the filaments distill in straight lines and cast well-defined shadows, because the mean free path at this pressure is greater than the diameter of the bulb, and it was natural to assume that this vaporizing carbon carried electric charges of negative sign. This assumption might seem to require the more rapid wasting away of the negative half of the filament than the positive, but no data are present to prove this. When condenser charges were superposed on this apparatus it was found that with the negative end connected with the negative side of the condenser, the condenser was at once discharged. When connected oppositely, it was not discharged. Current could pass as negative from the hot conductor or filament, but not from the cold plate, nor could positive current pass from either the hot or cold terminal.

In connection with this work of Fleming's, we have studied the effect of the condition of vacuum on the current, and also found that the presence of gas is necessary for this negative discharge. In general, the higher the pressure of the gas, when this does not exceed a few thousandths of a millimeter of mercury, the greater is the current. This makes it seem improbable that the current is solely dependent on the passage of carbon or tungsten from the filament to the positive electrode, though it leaves the possibility open that the current may be carried by gaseous ions produced by negatively charged material coming from the negatively charged filament.

By using alternating current and a metal electrode in a carbon lamp, Fleming obtained direct current on the circuit connecting the metal plate to either terminal of the lamp and the current was in the direction expected, the plate being negative to the terminal.

This outfit is thus obviously a rectifier, and it has been so used by Fleming for low currents.

The effect of a magnetic field on this gaseous conduction, just as in the case of metallic bismuth, is to increase the resistance.

It was finally found that the Crookes radiometer was a very sensitive gage for the changes of pressure in lamps, and by its use the changes could be followed in a qualitative manner, even throughout the life of the lamp, by having the radiometer sealed directly to the lamp. Dewar has shown the sensitiveness of this apparatus in the *Proc. Roy. Soc.*, 1907, 531.

The radiometer consists of a glass bulb containing a perpendicular needle with a glass cap on which are four aluminum arms with a mica vane at the end of each.[1] One face of each mica vane is coated with lamp-black. When the radiometer is evacuated to a high degree, the effect of radiant energy or light is to cause rotation, which is believed to be due to the fact that the molecules of gas take up energy from the blackened surface of the vanes more than from the plain surfaces, the black absorbing more of the incident energy and thus locally heating the gas molecules. These in the rarefied atmosphere largely give off this energy to the walls of the apparatus by direct impact, rather than to other molecules in the neighborhood of the vane. This results in a motion of the vane opposite to the motion of the gas molecules, because the unblackened face of the vane receives impact mostly from these cooler molecules.

The vacuum of the lamp as sealed from the pump approximates a few microns and is poor enough so that the radiometer rotates rapidly when exposed to light. By using a fairly constant light intensity and noting its effect upon a radiometer attached to a lamp which was lighted for intervals, it was seen that the radiometer gradually rotated more and more slowly, and finally after a period of normal lamp brilliancy of from 12 to 36 hours on tungsten lamps, it would stop rotating altogether. At this point it was found that a more sensitive measure of still higher vacua could be gained by starting in the dark, by mechanical motion a rotation of the vanes of a definite speed, and noting the rate of speed decay on standing. This was done by proper spinning of the whole apparatus in the hand and then getting the rate of decrease in this rotation of the vanes by counting definite revolutions after definite time intervals. Here the friction of the residual gases was merely overcoming the momentum imparted mechanically to the vanes at start. In this way, even by comparing the minutes required for the radiometer to come to a stop, quite interesting information was obtained.

This method was not developed into a quantitative one though it might have been. The radiometer method shows us, however, some interesting facts which are worth describing. Using the common type of radiometer often seen in jewelers' windows and sealing this directly to a lamp made for 110-volt circuit, the radiometer would rotate when in daylight. This showed the presence of some gas in the lamp, and the McLeod gage used at the time of sealing the lamp from the pump showed approximately 2 microns. If, now, the radiometer and the lamp were removed to a dark room and a rotating motion imparted to the vanes, they would proceed to rotate for about a minute, this time depending somewhat on the particular radiometer used, as well as on the condition of the vacuum.

Since at the moment when the filament was at bright heat and the vacuum very poor (so poor, in fact, that if the pressure were maintained constant the lamp would blacken in a few minutes), the vacuum greatly improved, due to some action occurring together with spattering of the filament, it seemed important to know more about the phenomena. We assume that the gas at first present goes to the walls of the lamp and is held there, possibly absorbed by the small quantity of deposited filament material. It is always possible to drive the greater part of it back into the vacuum space by warming the glass. It seemed perfectly possible that the process might be a cyclic one; that is, the gas carrying to the walls of the bulb some of the filament material and not of necessity remaining there, but possibly returning for a fresh supply. This continued process might account for the limited life of an incandescent lamp. It did not seem necessary to assume that there was any measurable rate of simple distillation from a carbon filament at the temperature of operation, though such a phenomenon could account for limited life of filament. It even seemed possible that the cyclic process, instead of being physical, might well be expressed as a chemical one, such as we know could exist, and might continue between the oxides of carbon and carbon itself. At the high temperature of the filament, carbon monoxid would be expected, but this, at a lower temperature, would form CO_2 and free carbon, the latter being deposited upon the glass. The free CO_2 coming into contact with the hot carbon filament would again form carbon monoxid, and thus the process be repeated continuously until the filament was burned through or the lamp became too black to be of use. It was therefore desirable to get a closer insight into the phenomena in the lamp at a pressure of a few microns.

Similar considerations can apply equally well to the case of tungsten filament lamps. In the case of osmium lamps this reasoning, extended, explains the fact that the presence of a little oxygen in the lamp was necessary to prevent blackening of the bulb by the deposited metal. A little oxygen in a carbon lamp might similarly remove deposited carbon from the glass and deposit it upon the filament, if the temperature at the two points were suitable, but with this element it seems impracticable because the oxid formed is not easily reduced below the CO state, thus differing from osmium.

While the lamp to which a radiometer was attached was not lighted, practically no change in vacuum could be detected by the radiometer. Therefore there is no leak of air from without. If, however, the lamp was lighted, the reverse was true. On allowing the lamp to be lighted for a few seconds only, and then cooling and testing in the dark room as before, the duration of rotation would usually be shorter, thus indicating a liberation of gas into the bulb space by this short time of burning. If, however, the lamp were allowed to burn at a normal brilliancy for a longer time and the same vacuum test was made from time to time on the unlighted lamp in the dark room, it was found that the duration of the impressed rotation rapidly increased. In many cases a rotation lasting 15 minutes would be produced by allowing the lamp to burn 24 hours. This phenomenon of automatic vacuum improvement received the name of the "clean-up." While the clean-up, as measured in this rough way, did not seem to take place in all lamps to the same degree, it was always present under ordinary conditions.

Other types of vacuum lamps improved their vacua on running. In fact, no lamp, unless we except the mercury arc, fails to do so. The well-known Moore tubular system of lighting, which is a development of the Crookes tube, consumes the gas, and for that reason an automatic valve was invented which supplies air to the tube when the vacuum improves to a certain point. It is also an old story, in the case of the cathode and X-ray tubes. X-ray tubes are usually made with a salt, such as potassium chlorate or potassium hydrate, mica, asbestos, etc., in an attached side tube. This may be heated when the tube in use attains too high degree of evacuation, and in this way gas is liberated into the bulb. This is in turn removed from the vacuous space by the operation of the tube. A natural question is raised at once: what becomes of these disappearing gases? In some cases they are probably forced or shot into the glass itself, for some of these old glasses bubble on being heated to the softening point. Possibly the greater part of the gas is absorbed by the exceedingly finely divided metal, which slowly deposits on the glass as it vaporizes from the electrode.

If an incandescent lamp, the vacuum of which had been thus cleaned up, was allowed to stand unlighted at ordinary temperature, the vacuum, as indicated by the test, would gradually grow poorer, though it would seldom fall to the starting value. If the bulb were heated in an oven at 100 deg. cent. for a few moments, it would also show a poor vacuum again on cooling. If such a spoiled vacuum lamp was again lighted, it would at once commence to recover its previous high vacuum. There was no indication of a fatigue evinced in lamps thus treated.

This explains the fact noticed in the case of most factory-made incandescent lamps, that their life at constant voltage varies with the external temperature. It is as though the gas, which is at first present in the space of the sealed bulb and is then thrown upon the walls by the clean-up, is also continually driven off from the walls at a rate dependent upon the wall temperature, and the deposition is bound up with some loss of filament material.

The experiments with the radiometers naturally led to attempts to develop more nearly quantitative apparatus which would still measure the low pressures of gas under consideration in incandescent lamps. Among the promising methods was that described by Pirani (*Ber. Deut. Phys. Ges.* 1906, 686). This was further developed by Dr. Hale of this laboratory, as described in the *Transactions* of the American Electrochemical Society, 1911.

This gage depends on the principal that energy loss from a heated wire in the vacuum to be measured depends on the pressure of the gas present. When the temperature of this wire is low (100 deg. cent., for example) the losses by radiation are relatively small, so that the rate of total loss at a constant temperature of wire would serve to determine the gas pressure. Conversely the temperature of this wire, if supplied with constant energy, from the battery, for example, would be higher, the lower the gas pressure. This latter scheme was adopted by Dr. Hale, and the gage consisted of a glass bulb sealed directly to the lamp to be measured and contained about two feet of fine platinum wire. This was heated by a current of constant watts and the temperature of the wire was given by knowing its temperature resistance coefficient and measuring the actual resistance for the case in test.

The measurement involved extrapolation towards perfect vacua from comparative measurements made with the new gage and the McLeod gage at pressures high enough so that the latter is reliable. Hale concluded that he could measure differences of pressure of one hundred-thousandth of a millimeter of mercury, or a hundredth part of the vapor pressure of mercury at zero centigrade. Here was a gage which, unlike the McLeod, exerted no appreciable vapor pressure of its own and therefore could serve to indicate the existing pressure at any period of the life of the lamp. It could disclose the fact if gases were produced within the burning lamp, if the seals or glass leaked at all, and how the clean-up actually changed the vacuum as indicated by the radiometer experiments. In using this gage new and interesting phenomena were disclosed, which must be further studied. In certain cases vacua a little more than perfect are indicated by this gage, and this suggests possible dissociation of the very attenuated gas. Barring this fact, it seems as though the clean-up effect proceeds to as nearly perfect vacuum as we can measure even qualitatively.

DISCUSSION ON "VACUA" (WHITNEY), BOSTON, MASS., JUNE 25, 1912.

A Member: Dr. Whitney refers to the gases which disappear from the incandescent lamp, and refers to the same phenomena in connection with the X-ray tube, and he calls attention to the fact that some of these old glasses from the old bulbs, either from the incandescent lamp or from the X-ray tube, bubble on being heated to the softening point. I hope that Dr. Whitney will clear up the claims of certain English physicists, and of German physicists, as to this matter. Dr. Robert Poole of the University of Berlin repeated some experiments made by an English physicist and he declares absolutely that the Englishman is mistaken; that an old glass does not give off this gas when it is under pressure in a vacuum so that the gas would be given off. Dr. Whitney refers to the fact that the glass when heated to a softening point will bubble, referring to the old glass, and I know a new glass does this as well, the conditions being that the old glass or new glass must be in a vacuum of something less than one millimeter actual pressure. I hope that Dr. Whitney will clear up this point, because the question of where the gas goes to is really a question that is important.

W. R. Whitney: I don't want to try to clear that up yet, because we don't know enough. There are various theories about it, but I cannot decide it.

Alfred H. Cowles: In a letter from A. H. Bucherer, of Bonn University, it is stated that in Europe they have a new method of creating a much higher vacuum than anything heretofore secured. I do not know whether that method is known in this country.

W. R. Whitney: As a further contribution to the question of gases within the glass of old X-ray tubes, lamps, etc., I will add that such gas also appears in the glass of old mercury rectifiers. Mr. Van Brunt, of the research laboratory, heated in a blast lamp the glass side-arms of old mercury rectifiers. The portions of the glass near the anodes turned white. On microscopic examination it was noted that this part of the glass was filled with minute bubbles which were not there prior to the heat treatment. They were within the glass itself, though much nearer the inner surface of the tube than the outer. This was shown by grinding and polishing in a plane which made a very acute angle with the surface of the glass. We did not consider the appearance of these gases in such glass an open question, but believe the question now is as to the source of the gas. Are these bubbles produced from gas which was dissolved or driven into the glass during the operation of the lamp or tube, or was the gas produced by a reaction between some injected material such as the electrode material and the material of the glass, or was it produced by the action of leakage current, static, etc., which caused a sort of electrolysis of the glass, the gaseous products remaining dissolved until the glass was subsequently heated?

UNITED STATES PATENT OFFICE.

EMMERSON L. CLARK, OF LAKEWOOD, OHIO, ASSIGNOR TO NATIONAL CARBON COMPANY, OF CLEVELAND, OHIO, A CORPORATION OF NEW JERSEY.

METHOD OF COATING PROJECTOR-LAMPS WITH REFLECTING-SURFACES.

1,121,802. Specification of Letters Patent. **Patented Dec. 22, 1914.**

Application filed January 11, 1913. Serial No. 741,[illegible].

To all whom it may concern:

Be it known that I, Emmerson L. Clark, a citizen of the United States, residing at Lakewood, in the county of Cuyahoga and State of Ohio, have invented a certain new and useful Improvement in Methods of Coating Projector-Lamps with Reflecting-Surfaces, of which the following is a full, clear, and exact description.

My invention relates to a method for internally coating an incandescent lamp with a highly reflecting surface.

In my application filed October 17th, 1912, Serial No. 726204, for incandescent light for projection apparatus, I have disclosed an improved form of projector lamp of the incandescent type.

This invention relates to a method of applying the reflecting coating on the interior of the incandescent lamp there disclosed.

Figure 1 is a more or less diagrammatic representation of means for coating an incandescent lamp with reflecting material. Fig. 2 is an end view of the arrangement shown in Fig. 1 with means for cooling certain parts of the lamp. Fig. 3 shows a modified form of the arrangement for coating the lamp. Fig. 4 illustrates a further modification.

If a source of light be partly surrounded by a diffused reflecting surface and the remaining area of the surface be composed of a medium pervious to light, all of the light emitted from the source must eventually proceed through such area provided the efficiency of the reflecting surface is 100%. That is, if all the light is reflected back and forth from the reflecting surface and none of it is absorbed, it must be all emitted through the light pervious area. However, a diffused reflecting surface of 100% efficiency is not at present obtainable, so that with the lamp constructed as described, the entire light emitted from the source would not pass out through the window or light-pervious area, but a certain amount would be absorbed. The concentrating effect produced by such arrangement can be approximately computed as follows: Let I be the mean spherical intensity of the extended source within the reflecting inclosure; let R be the reflecting co-efficient of the reflecting inclosure; let P be the per cent. area which is uncoated with reflecting material; let r be the radius of the inclosure (assumed spherical) then the intensity of the illumination produced at the light-pervious area or window is:

$$\frac{I}{r^2}\times\frac{100}{100-(R-P)}$$

If, instead of a diffused reflecting surface, a polished surface is used so that specular reflection is had and the interior surface of the bulb is perfectly smooth and exactly spherical, not all of the light from the source would be emitted through the window. Since the reflecting surface would be everywhere symmetrical in regard to the source of light, a ray of light once reflected would continue to be reflected in the same plane. The planes of reflection would include the great circles of the spherical bulb. This means that only that part of the light would finally reach the window that was reflected in the plane of the great circles that intersect it. But even with specular reflection, the intensity of light would be greatly increased at the window. However, in practice, it would be impossible to obtain a bulb with such an exact interior surface that the light rays would continue to be reflected in the plane in which they started. As a matter of fact, the interior surface would consist of minute surfaces facing in diverse directions. This would be sufficient to cause all light to be eventually reflected through the window so that the light emitted through it would follow somewhat approximately the law of diffused reflection. The interior of the bulb may be made with an irregular surface to cause the light to more closely follow this law. From the law of diffused reflection, it will thus be seen that a slight increase in the reflecting co-efficient makes a large increase in the light emitted through the window. In my application above referred to, the invention is directed broadly to any form of reflecting medium. I have since found that metallic sodium and potassium have very high reflecting co-efficients, being in the neighborhood of 99.7. Their reflecting property is thus almost perfect. Substituting this value in the equation for diffused reflection, we get an intensification of approximately 77 at the window, assuming a window of 1% area. As explained above, the metallic surfaces would not follow exactly the law for diffused reflection, but would have a value somewhat less than that obtained by it. As stated above, the bulb could be coated with a roughening material or be made with rough and irregular protuberances so as to more closely follow this law. Since sodium or potassium oxidize very readily when in the presence of oxygen, it will be necessary to apply the coating with no trace of oxygen. I accomplish this result as follows:

Referring to Fig. 1, the incandescent bulb 1 which may be glass or metal as in my prior application, is connected to a container 2 by means of a tube 3. The container is connected to means for producing a vacuum through pipe 4. The vacuum pump or other means is not shown on the drawing. The container 2 contains the sodium, potassium, or other metal. This container may be a glass tube having restricted ends 3 and 4 connected to the bulb and pump respectively. After the incandescent filament is placed in the lamp, the air is exhausted through the tube 4 and the latter sealed. The sodium or other metal in the container 2 is then heated by any means, a gas jet 5 being shown for the purpose of illustration. The sodium or other metal is vaporized and passes up into the lamp bulb where it is condensed on the interior surface. In order to prevent the metal from condensing on the window 6, heat should be applied thereto. The window may be heated in any manner but I have shown a heating coil 7 closely adjacent thereto and connected to a source of E. M. F. 8. It is also best to send current through the filament 10 in order to prevent the metal from condensing there. After the metal has condensed on the interior of the bulb, the glass tube 3 is sealed off in the usual manner. The bulb is thus provided with a highly reflecting coating of sodium or other metal with the exclusion of oxygen, and it retains its brilliant surface indefinitely. The lamp, when thus coated with sodium or potassium, furnishes a much more concentrated light than with all other known reflecting coatings. In order to more efficiently coat the interior of the bulb, it will be advisable to cool the parts of the lamp to which the coat is to be applied. In Fig. 2, I have shown such an arrangement. Water or other cooling medium is circulated through jackets 11, 12, which may be hemispherical. The water jackets are shaped to leave openings for heating coil 7, the connecting plug 13 and the tube 3. With the cooling means shown, the deposit of metal will be more regular and the window will have a sharper contour. If desired, the lamp bulb may be coated while placed in a draft of cool air to cause the deposit of metal.

In Fig. 3, I have shown a further method of preventing the metal from depositing on the window 6. A disk 14 is placed in the bulb before it is sealed up. This disk is of the same size as the window desired, and is coated on one side with some material such as soft varnish or felt to prevent its scratching the reflecting surface after the lamp is complete. Before the sodium or other metal is vaporized, the lamp is turned until the disk 14 slides into the proper position, and then the air is exhausted and the metal vaporized. The metal will condense on the interior of the bulb and on the upper surface of the disk 14 but it will not condense on the window 6 because it is covered by the disk. After the coating process is complete, the lamp is turned so that the disk 14 slides off the window. In this way the interior of the bulb is coated with sodium or other metal, leaving a sharply defined window entirely free from the coating. The reflecting efficiency of the bulb is not impaired by the disk inasmuch as the upper surface of it is coated with reflecting material. Of course, care should be used in handling and in shipping to prevent the disk from turning over with the reflecting surface downward. In this arrangement, current may be sent through the filaments to prevent the metal from condensing thereon and the bulb may be cooled as in Fig. 2.

In Fig. 4, I have shown a still further modification. The lamp here shown is intended for a headlight on automobiles or other carriages. It consists of a body portion 15 having a substantially parabolic shape and a transparent portion or window 16. The window 16 may be sealed on to the body portion 15 in any well known way. The light emitting filament used in this type of lamp consists of a helix of thin tungsten strip or foil coiled flatwise with leads 17 and 18 as shown. By using the thin strip or foil, I am able to concentrate the light source at the focus. The interior of the body portion 15 is to be coated with sodium or other metal and the window 16 is to be uncoated. As a variation of the method above described, I may use mercury, oil or other liquid to prevent the metal from depositing on the window 16. The liquid may be introduced into the lamp through tube 19. After the air is exhausted from tube 3, the sodium or other metal in the container 2 is heated and is condensed on the interior of the body portion 15. This body portion may be cooled as previously described. The sodium may be allowed to condense on the mercury if such is used, forming an amalgam therewith. After the coating is applied, the mercury or other liquid is withdrawn through tube 19 and it, as well as tube 3, is sealed. In this way, the sodium is prevented from depositing on the window 16. This form of light may be used very efficiently with dry cells for instance. In this modification, the mercury or other liquid may be withdrawn through tube 3 after the sodium has vaporized and the tube 19 dispensed with.

I do not claim to be the discoverer of the fact that sodium and potassium have very high reflecting co-efficients, but I believe I am the first to disclose the method described for applying coatings of such material to the interior of incandescent lamps.

Having described my invention, what I claim is:

1. The process of coating a bulb with a reflecting surface which consists in freeing the interior of oxidizing gas, heating a supply of the coating material and causing the vapor thereof to condense on the interior surface of the bulb.

2. The process of coating a bulb with a reflecting surface which consists in freeing the interior of oxidizing gas, heating an external supply of the coating material and causing the vapor thereof to condense on the interior surface of the bulb.

3. The process of coating a bulb with a reflecting surface, which consists in freeing the interior of oxidizing gas, leading a supply of vapor into the interior and causing it to condense on the greater part of the interior surface while preventing it from depositing on the remaining surface.

4. The process of coating a bulb with a reflecting surface which consists in freeing the interior of oxidizing gas, heating a portion of the bulb, heating a supply of the coating material and causing the vapor thereof to condense on the interior surface of said unheated portion of the bulb.

5. The process of coating a bulb with a reflecting surface, which consists in freeing the interior of oxidizing gas, heating a portion of the bulb, cooling the remaining portion and heating a supply of coating material so that the vapor thereof will condense on the interior surface of said cool portion of the bulb.

6. The process of making a bulb with reflecting surface which consists in forming the bulb, roughening the interior surface, freeing the interior of oxidizing gas, and causing a vapor to condense on the interior surface.

7. The process of making an incandescent lamp which consists in forming the bulb, adding the filament, exhausting the interior, heating the filament, and a portion of the bulb and causing a vapor to condense on the interior surface of the unheated portion.

8. The process of making an incandescent lamp which consists in forming the bulb with a roughened interior surface, adding the filament, exhausting the interior, heating the filament and a portion of the bulb, and causing a vapor to condense on the interior surface of the unheated portion of the bulb.

9. The process of making an incandescent lamp which consists in forming the bulb, roughening a portion of the interior surface, adding the filament exhausting the interior, heating the filament and the non-roughened portion of the bulb and causing a vapor to condense on the said roughened surface.

10. The process of coating a bulb with a reflecting surface which consists in freeing the interior of oxidizing gas, placing a movable cover over a portion of the interior surface heating a supply of the coating material and causing it to condense on the interior surface of the uncovered portion of the bulb.

In testimony whereof, I hereunto affix my signature in the presence of witnesses.

1. CONCERNING THE PRESSURE OF CATHODE RAYS.

By ERNEST V. ANGERER.

[1]

With William Crookes[1] originated a celebrated experimental arrangement with which he believed it possible to detect the mechanical impact of cathode ray particles; in a vacuum tube is enclosed a small paddle-wheel whose axis runs on two glass rods. Two electrodes are so arranged that the cathode rays emitted from one of them impinge on the uppermost blade. It then resulted that the wheel rolled forward when subjected to radiation from the cathode. As Crookes assumed, under the influence of "materie radiante".

Later Puluj repeated this investigation and devised another experimental arrangement.[2]

Furthermore E. Riecke[3] has published a quantitative investigation of this problem. He measured the counter impact imparted to the cathode by the ejected electrons. Of Riecke's results the most important is that (under the assumption of $\varepsilon/\mu \sim 10^7$ electromagnetic units) the intensity of the cathode rays would have to be about 80 times as great as the intensity of the total current in order to account for the mechanical action. In reality it could amount only to a small fraction of the total current.

Finally there is an experimental investigation by [2] Starke[4] in which Starke showed that the effects which took place in the above mentioned work demanded much greater forces than those called into existence by the impact or emission of electrons.

He recalls a work of Warburg[5] who finds that in gaseous discharges the cathode is subjected to forces which may amount to 10^4 times the expected effect. Besides the observed turning moment admits of explanation by electrostatic forces and also in particular by a radiometer action from the surface of the heated blade.

The pressure p in its relation to the number n of the electrons (e) and the accelerating potential V is given by the following formula which admits of easy derivation

$$p = \frac{n \varepsilon \sqrt{2V}}{\sqrt{\frac{\varepsilon}{\mu}}}$$

$n . \varepsilon = i$ can be measured with a galvanometer. If we take for ε/μ a new value for the most recent work.

$\left(\frac{\varepsilon}{\mu}\right)$ 5000 volt $= 1.74 \times 10^7$ electromagnetic units then, for example at $V = 5000$ volts $= 5 \times 10^{11}$ electromagnetic units and $i = 10^{-5}$ amperes $= 10^{-6}$ electromagnetic units.

$$p = \frac{10^{-6} \times 10^{+6}}{4.17 \times 10^3} = 3.40 \times 10^{-4} \text{ dynes.}$$

The torsion balance was placed by Starke in an electrostatically shielded space and connected through a galvanometer to ground. In order to avoid as much as possible disturbances from radiometer action, he utilized very thin sheets of foil as receivers (targets) in the expectation that the temperature of the absorbing front surface would then differ little from that of the rear surface. In spite of this he got too large deflections which became smaller with higher evacuation. To exclude [3] radiometer action with certainty he employed instead of the torsion balance a circular disk of aluminum foil which by the impact of the obliquely incident cathode rays was rotated on its vertical axis while the radiometer force, acting perpendicularly to the surface, tended to turn the disk on a horizontal axis.

With this arrangement Starke obtained scale deflections of several millimeters but the deflections were so irregular that he could not accurately measure them. As a result of his investigation he gives the observed pressure under a radiation of 10,000 volts and 10^{-7} amperes as less than 10^{-4} dynes (calculated 2.0×10^{-6} dynes).

During the twelve years which have passed since this work of Starke's our knowledge of cathode rays has been extraordinarily widened by experiment and theory. Since Joffé6) has recently shown the magnetic action of cathode rays, the measurement of its radiation pressure is the only fundamental research which has not been satisfactorily carried out. On the other hand the experimental technique has undergone substantial improvement; we can by aid of Dewar's coconut charcoal produce very high vacua in which radiometer effects are very small, we can also by means of the Wehnelt oxide cathode produce intense cathode rays in high vacuum and finally we can exactly measure low gas pressures of this order with the absolute manometer of Knudsen.

I have therefore taken up again the investigations of Starke. Unfortunately as yet I have no decisive results to offer. Since, however, my work must be interrupted for other reasons, it may be permissable in the meantime to publish the results already reached.

DESCRIPTION OF THE EXPERIMENTAL ARRANGEMENT.

The Cathode Ray Apparatus of the Preliminary Experiment.—It seemed the most promising to repeat Starke's experiments with the disk. The disk S (Fig. 1) [4] consisted of aluminum foil of 0.008 cm. thickness and had a diameter of 3.4 cm. It was coated with rust7) and dusted with a rather finely pulverized "Sidotblende" to disclose the point of impact R of the cathode rays. In its center was soldered a hard drawn brass wire which supported a mirror. This system was suspended by a "Wollaston" wire of 0.007 mm. thickness and had a vibration period of 23 seconds. It was insulated and suspended in a brass box F which was fitted into a glass vessel G. The cathode rays left the Wehnelt cathode W,8) passed through an opening in the box and fell upon the disk at a near angle of 45°. A shield A which was placed in part of the box, served as an anode. The anode, the Faraday cage, in which the rotatable disk hung, and the latter itself were all insulated from one another and connected individually to ground and a galvanometer could be inserted in each of the circuits to ground. In this way the intensity of the absorbed as well as the reflected rays could be measured.

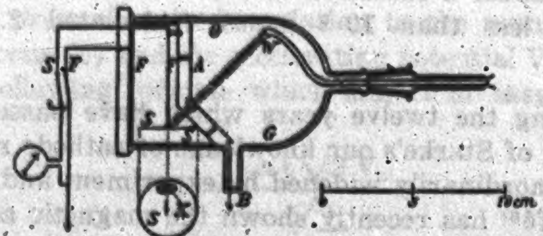

Fig. 1.

The vacuum was produced by charcoal in liquid air and measured by means of a Knudsen galvanometer whose final form is described later (p. 10). The tube B led to the pump, the charcoal container and to the manometer.

Experiments with this apparatus gave the following results:

A vacuum of about 0.0001 mm. Hg was maintained, while the cathode was in activity. The rays are emitted [5] not in a narrow bundle as at high pressures, but diverge greatly from the cathode. The current derived from the disk was about 10^{-5} amp. The intensity of the reflected rays was (at 3000 volts) just as great as that of the absorbed rays. When the Wehnelt cathode glows, the disk turned about 90° in the absence of any cathode rays. When voltage was applied, so that cathode rays impinged upon the disk, the deflection was greater.

It is evident that this rotation was due to a radiometer effect between the glowing platinum sheet and the disk. A small part of the gas molecules which were ejected in all directions from the cathode at the high velocities corresponding to their high temperature, struck the rotating disk through diaphragms. It need only be assumed that the surface of an aluminum cathode such as used by Starke is hot, in order to attribute the deflections observed by him to the same sources of error.

In order to eliminate disturbances, the hole in the anode shield was closed through aluminum foil which was as thin as possible. The rotation did not disappear entirely, as the foil becomes heated by radiation and so a small difference in temperature remains between it and the disk.

One is inclined to explain the greater angle of turn given the disk when cathode rays start, as the effect of their pressure. But this conclusion is not admissable for as Wehnelt and Jentsch[9)] have shown, the temperature of a glowing wire may rise when it emits cathode rays (because positive ions fall upon it). This rise in temperature may cause the greater deflection, as shown above. To perform the experiment properly, the cathode rays would have to be deflected to one side by a magnet, until the disk has taken a position and then the rays be permitted to fall on it. This could not be easily done [6] with the apparatus described owing to the strong divergence of the rays.

One great disadvantage of this arrangement is the strong reflection of the cathode rays occurring when the angle of incidence is acute. For the reflection, as is well-known, is neither strictly geometrical nor completely diffuse[10] the receiver may even emit more electrons than it receives.[11] For accuracy, it is desired that all the electrons possible be absorbed. Since the rotating disk corresponded so little to this requirement the experiments were stopped in order to set up a new arrangement for avoiding the above errors as much as possible.

The Final Cathode Ray Apparatus.—It should be noted that careful attention must be given to the elimination of electrostatic disturbances. For the potentials on the tube may easily affect a sensitive torsion balance. In apparatus, which will not be described here, cathode rays were made to fall on the wall of a glass tube and the latter attracted the torsion balance; in other experiments two (freshly ground) aluminum wires of the balance made a contact in the atmosphere but not in a vacuum so that the torsion balance was charged. With the apparatus to be described, which is illustrated in Fig. 2 and used for the later experiments, the above errors were avoided as much as possible.

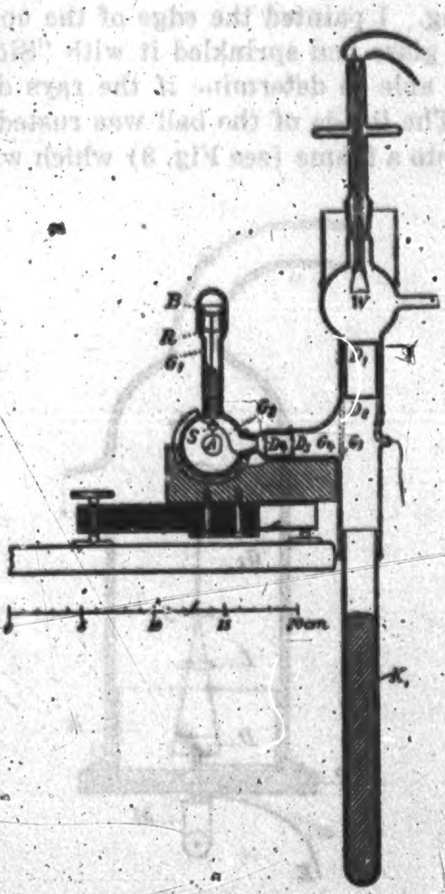

Fig. 2.

a. *The Torsion Balance.*—A Faraday cage was used as the receiver of the torsion balance in order to avoid as much as possible the disturbing reflection of the cathode rays.

The receiver A consisted of a hollow aluminum sphere 16 mm. in diameter, which had a round hole 9.4 cm. in diameter. To the ball were soldered two thin, hard drawn copper wires.12) The ball was etched with concentrated caustic potash until the thickness which was originally 0.5-0.8 mm. had been so reduced that at points small holes were made; it then weighed about

[7] 120 mg. I painted the edge of the opening with a little water glass and sprinkled it with "Sidotblende" in order to be able to determine if the rays did not touch the edge. The inside of the ball was rusted. The wires were bent into a frame (see Fig. 3) which was reinforced

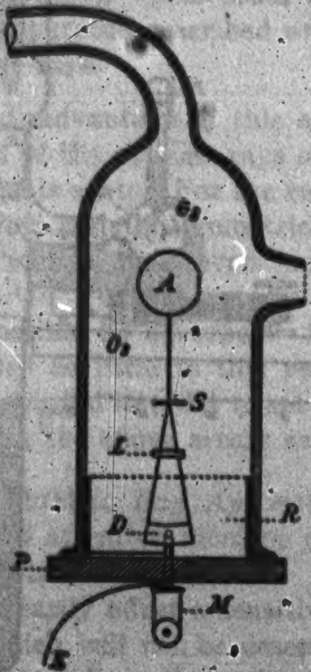

Fig. 3.

and supported a mirror S in the middle while at the end farthest removed from the ball it supported a small piece of sheet silver D, which vibrated between the poles of a small electromagnet M with a damping which could be regulated. With the mirror the torsion balance weighed 510 mg. L is a small sliding weight of copper foil which was necessary to bring the opening in the ball in the path of the rays and at the same time to make the silver disk oscillate freely between the magnet poles separated by 0.8 mm. *The distance from the axis of rotation to the middle point of the ball was 3.0 cm.* This system was suspended by a well gilded hook from a Wollaston wire 0.015 mm. in diameter and 54 mm. long, and its period of oscillation was 42.3 sec. A gilded brass ring R which was clamped to the glass tube C_1 (Fig. 2) and provided with a grounded wire leading outward, was used as the torsion head. On this ring was placed an iron, gilded crossbeam B in the middle of which the suspension wire was fastened. By bringing a magnet close, the beam B and with it the vibrating system could be turned. The glass vessel G_2 containing the torsion balance was fastened, together with a wooden base cut out in a corresponding manner, to a tripod equipped with adjustable screws. To the polished front surface of the container a mirror plate P was soldered containing two holes for the poles of the damping magnet M. G_2 was silvered inside and rusted and was electrically connected with the iron of one pole by means of a brass ring R. On the outside of the mirror plate a wire E led from this pole directly or through a galvanometer to ground.

b. *The Discharge Tube.*—The cathode rays had to be separated from the gas molecules ejected from the Wehnelt cathode, which had caused such disturbances [8] in the first apparatus, by a *magnetic field.* For this reason the discharge tube G_3 was placed vertically. Opposite the glowing cathode and not separated from it by narrow canals, was the carbon K_1 which was cooled with liquid air. At the low pressure used, the mean free path was considerably greater than the distance from the cathode to the carbon so that most of the gas molecules were hurled to the absorbing surface of the carbon without colliding with others. On the other hand a magnetic field whose lines of force are to be imagined perpendicular to the plane of the drawing deflected the cathode rays to the horizontal branch G_4 which was soldered to the container G_2.

[9]

The *Wehnelt cathode W* consisted of platinum foil 0.005 mm. thick which had been glowed out then pressed into a round cup. It had been found that the divergence of the rays was minimized by using a hollow cathode of this kind. The metal was heated by electricity and a crystal of calcium nitrate melted in it. It was important to have a uniform coating of calcium oxide which was not too thin. The surface of the oxide spot was about 0.3 cm². On the glass sphere inclosing the cathode was soldered a tube filled with cooling water.

The rays then hit diaphragms D_1 and D_2 which formed the anodes, were bent, passed through diaphragms D_3 and D_4 and finally reached the inside of the aluminum ball to be absorbed.

The magnetic field was produced by a horse-shoe electromagnet the exciting current of which could be controlled within wide limits from the observer's position by a regulating resistance.

The discharge tube G_3 and G_4 was silvered over on the inside as far as the diaphragms D_1 or D_4. The diaphragms were in the form of caps pressed from copper 0.9 mm. thick, and they fitted into the tube under strong tension. Immediately before being inserted they were cleaned with concentrated nitric acid, washed with distilled water and dried. They were electrically connected by the layer of silver and were grounded with it through D_2. After the diaphragms were inserted, the tube G_3G_4 was coated inside with rust.

The discharge tube was insulated from the container G_2. The circuit was arranged so that a galvanometer could be put in the circuit of the grounded line from the torsion balance or in that from G_2 containing the balance as in previous experiment.

DETERMINATION OF THE DIRECTION OF THE FORCE OF THE SUSPENSION WIRE.

We shall calculate the force perpendicular to the axis of rotation at a distance k from it which causes by rotating the system a deflection of the image in the mir-
[10] ror amounting to the angle α.

For this purpose a pendulum instead of the torsion balance was suspended on the Wollaston wire; this consisted of an aluminum wire 8.41 cm. long, 1.390 mm. in diameter, and weighed 0.221_5g. Its moment of inertia K was therefore 1.306 g x cm². In the middle was a very light hook of glass thread. The period of oscillation of the wire was $t = 16.10$ sec.

By combining the two formulæ for the determination of the modulus of torsion by oscillation and by torsion[13] we have:

$$D = \frac{\pi^2 R \alpha}{h t^2} \text{ dynes.}$$

Since in all experiments the perpendicular distance between the mirror and the scale was 1705 mm., the arc value of one millimeter of the scale in absolute measure is:

$$\alpha \text{ mm} = \frac{1}{2 \times 1705}$$

Accordingly, the force at the point of impact of the cathode rays ($h = 3.0$ cm.) which causes a scale deflection of 1 mm. is:

$$D = \frac{\pi^2 \times 1.306}{3.0 \times (16.1)^2 \times 2 \times 1705} = 4.8_{61} \times 10^{-6} \text{ dynes.}$$

The Knudsen Absolute Manometer.—At pressures which are so small that the mean free path of the molecules is large in comparison with the dimensions of the container, *the disturbing radiometer force* to which the blade of the torsion balance is subjected is *proportional* to the number of molecules and hence *to the gas pressure. The true radiation pressure (in an absolute vacuum) can therefore be found from the decrease in the apparent cathode-ray pressure with the gas pressure.* Then in order to calculate it the ratio of the (very slight) gas pressures during the experiments must be known.

An instrument which measures more accurately the
[11] pressure in question is Knudsen's "absolute manometer"[14] which measures the radiometer force between two plates of different temperatures in a vacuum. As just mentioned this force is proportional to the gas pressure provided that most of the molecules pass from one plate to the other without colliding. On this hypothesis Knudsen derives the following formula:

$$\text{The unknown pressure } p = \frac{2\,K}{\sqrt{T_1/T_2} - 1}$$

This equation assumes the following more simple form if the difference in the temperature of the plates is small in comparison with their absolute temperatures:

$$p = 4k\,\frac{T_2}{T_1 - T_2}$$

K is here the force with which each square centimeter of the movable plate is repelled and T_1 and T_2 are the absolute temperatures of the plates.

2

Knudsen demonstrated experimentally the correctness of his formula for different gases and different temperatures. In the work noted he gives five different forms of the manometer without explaining the details of construction.

The fourth arrangement gives the greatest sensitivity, as he considers, and this is illustrated diagrammatically in Fig. 4 as seen from above. A are two platinum foil strips which can be heated by electricity. B is a mica plate which repelled by both strips turns about the axis 0. It is suspended by a fine thread at 0 which is to be imagined perpendicular in the plane of the drawing. In my first instrument of this kind the platinum foil was stretched taut by a brass frame. High vacua could not be obtained with this manometer, probably because of the relatively large masses of metal in it which constantly give off some gas. In the final form shown

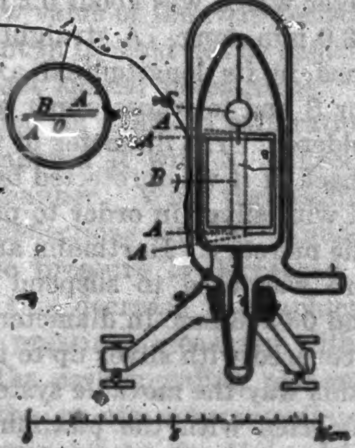

Fig. 4. **Fig. 5.**

in Fig. 5 as little metal as possible was used. The instrument was soldered to an iron tripod with adjusting [12] screws. At the top and bottom of the frame shown as cross hatched, which consisted of glass tubing, two horizontal platinum wires were fused which were separated from one another by the thickness of the glass tube (3 mm.). To these wires were soldered with silver strips of platinum foil 0.005 mm. in diameter. The left strip projects 1.5 mm. in front of the plane of the drawing and the other the same distance behind it. The heating current entered at the lower left-hand side by the left strip, was conducted through the two upper wires to the upper end of the right strip and was led out at the lower right hand. In order to prevent a short circuit between the lower wires a piece of fuse glass was inserted between them and the strips. The strips are 37.7 mm. long, 10.6 mm. wide and the distance between their inner edges, 5.0 mm. Including the leading in wires their resistance was 0.4 Ω.

A platinum wire was fused to the highest point of the cross hatched glass frame and the movable system was suspended by it. The latter consisted of a mica plate B coated with silver which was about 0.2 mm. thick, 26.7 mm. wide and 33.0 mm. long. A straight piece of brass wire was fastened in its longitudinal axis which supported the mirror S and to whose upper end the suspension wire was soldered. The diameter of the mirror was 10 mm. and the back of it was protected by a glass which was also covered with silver in order to prevent any disturbance from the mercury. Hartmann and Braun phosphor bronze wire was used to suspend it, which was 15.0 mm. long and 0.0208 mm. in diameter.[15] The glass framework was covered with silver up to the upper platinum wires. In this way the movable system was conduc- [13] tively connected with the platinum strips. The oscillation period was 1.68 seconds.

After the glass frame had been mounted in the manner described it was placed in the outer glass tube (not shaded) into which it fitted with precision. Then the leads being passed through thin capillary tubes which were sealed on, were sealed in and finally the upper opening of the outer tube was sealed and blown to form a hemisphere.

Opposite the mirror was a plane glass plate which by a special process in accordance with a communication from Herr Gundelact von Zeiss was fused on with the aid of cement. But since the sealing composition only withstands a temperature of 60° at the most and furthermore is attacked by benzol, the Zeiss process does not appear to have substantial advantages over the use of plain sealing wax.

In using this instrument we assume with Knudsen that the movable plate maintains its initial temperature T_1. We will later (p. 15) see how far this assumption is fulfilled. The temperature of the platinum strips was to be calculated from their increase in resistance. But later experiments showed that at the minimum pressures reached the movable system was strongly deflected when the excess temperature amounted to only a few degrees. Owing to the low value of the strip resistance an increase of a few per cent in it could not be sufficiently accurately measured without special precautions. For this reason I had to abandon an absolute calibration of the manometer, and compared it with a McLeod manometer in the following manner: With the heating current held constant the deflections of the Knudsen manometer diminish as the pressure is decreased from a certain maximum. If this decrease is graphically represented by plotting the pressures measured with the McLeod as abscissae and the corresponding manometer deflections as ordinates, the points corresponding to the lowest pressures determinable by the McLeod lie on a straight line which seems to pass through the origin. This [14] straight line was used for exterpolating to the lowest pressures which could not be measured by the McLeod manometer, but could be by the Knudsen. This method is not reliable for it is based on the hypothesis that with a constant heating current the temperature of the strips remains constant, even when the gas pressure varies. And this is by no means the case.[16)]

No other means was left except to measure the temperature of the strips by a thermocouple made of an iron and a constantine wire 0.050 mm. in diameter and touching one of the platinum strips in the upper third part of its distance, the soldered joint forming a feeble spring. The couple was connected with a moving coil galvanometer which gave a deflection of 7:45 divisions per degree of temperature difference.

In order to calculate the sensitiveness of the manometer the method described on p. 10 was used. The pendulum used here had a moment of inertia of 6.45 g x cm² and a vibration period of 9.5 seconds. The weighted points of the surfaces of the mica sheets were 0.9757 centimeters from the axis. This gives the value of one scale division as 1.754 x 10^{-4} dynes.

The "effective surface" on which the sheet mica and the platinum foil stood opposite one another was 6.6 cm² (both blades) and one scale division amounted to 1.5 mm. With these values the unknown gas pressure which makes a deflection of α scale divisions is given in accordance with Knudsen's formula:

$$p = \frac{\alpha T_1}{T_2 - T_1} \; \frac{4 . 1.745 . 10^{-4}\, 1.5}{6.6} = \alpha \frac{T_1}{T_2 - T_1}\, 1.5_{93}\, 10^{-4} \text{ dynes/cm}^2$$

$$= \alpha \frac{T_1}{T_2 - T_1}\, 1.2\, 10^{-7} \text{ mm Hg.}$$

In one example the spot of light was deflected 1.2 scale divisions and the thermocouple galvanometer 410 scale divisions, corresponding to 55°. This gives the following:

$$p = 1.05.10^{-3} \text{ dynes/cm}^2 = 7.6.10^{-7} \text{ mm Hg.}^{17)}$$

Calculation on the basis of calibration by the McLeod [15] manometer (see p. 13) gave 3.6 x 10^{-6} mm. of mercury. Since the temperature becomes greater than assumed as the pressure is decreased, the pressure values are too high. The pressure of the radiation emitted from the heated platinum strip in this experiment is calculated (under simplifying assumptions) as 7.2 x 10^{-5} dynes, or 5.2 x 10^{-8} mm. of mercury, and hence is negligible.

When the maximum radiometer effect was obtained (by choosing the proper pressure) the thermocouple galvanometer gave a reading 4.5 scale divisions $= 0.6_{05}$ degrees and at the same time the manometer gave a reading of 112 scale divisions. It follows that the optimum radiometer effect is 8500 times as great as in the first example (at the lowest pressure reached).

The two following checking tests made with the instrument may be mentioned:

We determined whether at a constant pressure the deflection of the spot of light was proportional to the difference in temperature. The following values were obtained.

Intensity of the heating current	0.2	0.3	0.5	Amps.
Temperature difference $T_1 - T_2$	7.94	14.4	53.1	Degrees
Manometer deflections	3.0	7.0	19.5	
Pressure (calculated)	1.31	1.39	1.28x10^{-5}	mm. Hg.

As one observes the pressures vary 4.5% from the average, but do not display any regular tendency.

We then endeavored to determine how rapidly the movable mica plate is heated by radiation and convection. The heating effects a reduction in the temperature difference $T_1 - T_2$ and this is not taken into consideration. Therefore during a long period of heating the measured pressures are too low. This is illustrated by the following table:

Readings - - -	1	2	3	4	5	Min. after heating current is stopped
Temperature of the platinum strip exceeding its surroundings	51.1	55.4	57.9	59.2	60.3	degrees
Manometer deflection - - - - -	18.7	20.0	20.4	20.8	21.0	Scale div.
Pressure calculated	1.06	1.05	1.02	1.02	1.01 x 10^{-5}	mm. Hg.

The pressure which was actually kept constant is therefore measured 5% too low 5 minutes after the current is started. [16]

The great advantages of a Knudsen manometer are that its range covers the lower pressures better than the McLeod manometer, and especially that changes in pressure are indicated almost instantly. A disadvantage is that the pressure can not be read directly from the scale deflections but must be calculated from the readings of two instruments. I have also found it especially disadvantageous that with the chosen construction the final temperature of the wire loops is not reached until about a quarter of an hour after the heating current is stooped. Only when the heating current is reduced through a loop of wire so that the thermocouple shows a constant temperature does the spot of light come to rest at a constant pressure. The instrument used by Koenigsberger and Kutschewski[18)] only known to me later is free from this complication. But it has a disadvantage that the surface of the warm plate opposite the movable plate, contrary to the requirements of the theory, has a very small extent and a possible disadvantage is the fact that the hot water is put into the instrument in the neighborhood of the electrostatic high voltage.

DEVICE FOR PRODUCING THE VACUUM

The high vacuum which was a fundamental condition for the success of this research was obtained by Dewar's method of the absorption of the residual air by means of cooled coconut charcoal.

The charcoal employed was obtained from Kallbaum from the shell of a coconut. To remove the tar contained in it it was heated for several hours in a nitrogen current (until it gave off no more combustible vapor). Then it was placed in the absorption tubes (each 34 g.), cut [17] up in small pieces and carefully freed of dust. These cylindrical tubes of glass of a very high melting point 25 mm. in diameter and 270 mm. long could be heated in an electric furnace built for this purpose to red heat (about 650°) and then fitted in the neck of Dewar flasks of 2 liter capacity. First one and then the other carbon could be connected with the pump through a triple cock, and finally the two carbon retorts could be connected together. If then one of them (the "front carbon") is cooled with liquid air it absorbs from the other one (the "principal carbon" of the discharge tube), which was at a high temperature, the last residuum of air, (later the principal carbon as long as it was heated was evacuated by the pump and for about 15 hours before the experiment was connected with the cooled front carbon). In the last part of the experiment I had a Gaede pump. It was necessary to heat the carbon until the initially noticeable emission of gas had become so slight that the pressure did not rise noticeably in the first vacuum of the Gaede pump in an hour's time. This occurred after 5-7 hour. If the heating was interrupted earlier and continued on the next day the pressure was much lower if the carbon had again reached the same high temperature and the carbon gave off less gas per unit of time than when the experiment was interrupted. If the amount of gas evolution had become imperceptible it could again be started by raising the temperature. For this reason and because the gas was liberated more rapidly, I used as high a temperature as possible, which resulted in distorting somewhat the walls of the carbon retort owing to the external pressure. Whether a still higher vacuum could be obtained by higher temperatures, or how much gas remains behind when this method is used could not be determined.

White sealing wax was used for soldering purposes [18] as furnished by Liliendahl-Neudietendorf. The cock was packed with a very tough "Gummifett" used by Ramsay.

THE REST OF THE APPARATUS.

A Du Bois Rubens armored galvanometer was used to measure the current intensity i. Its internal rseistance was 4142 ohms. The frequency of the (weighted) system was chosen as small as possible and the damping was measured so that the spot of light came to rest 5 seconds after the circuit was closed. The sensitiveness was 3 x 10^{-9} amperes per scale division. For the galvanometer and the Knudsen manometer an abjective reading was preferred, the two spots of light playing on the same glass scale. For generating the cathode rays we had a high potential storage battery of 3000 volts and a Toepler influence machine of 30 plates driven by a motor. The voltage at the terminals of the tube was measured by a Kelvin electrometer for 20,000 volts which had previously been connected by the writer with the Kirchhoff balance to the standard cell. The heating current for the Wehnelt electrode was furnished by a small local battery of four cells. Since the anode was grounded this heating current circuit had to be charged to a high potential to ground. The cells and a small Ruhstrat variable resistance were highly insulated by porcelain insulators. Finally a box was constructed of metal and grounded which contained the entire vacuum apparatus and left only the discharge tube outside.

EXPERIMENTS.

In general, good results were obtained with this arrangement so that it appeared that a quantitative solution of the problem might be possible. However, various defects still showed themselves which I did not succeed in overcoming until I was about to stop this investigation.

1. One substantial advantage over the former arrangement was that much higher vacua could be ob-

tained. The lowest pressure which I have measured was 8×10^{7} mm. Hg. (of the example of p. 14). The [19] lowest pressure found by the Reichsanstalt19) which can be obtained with coconut carbon and liquid air was 7×10^{-6} (As measured with a McLeod manometer). Of course, these values for vacua of such high order must not be accepted without careful criticism. For instance, it must be remembered that in such cases where the free paths are much greater than the dimensions of the apparatus the pressure is not the same in the parts of the apparatus which are of different temperatures but that rather the pressures according to Knudsen 20) vary as the roots of the absolute temperatures. (In the tube cooled with liquid air the pressure is only half as great and in the neighborhood of the glowing cathode it is greater than in the other parts of the apparatus which are at room temperature). Further, it is not impossible that the platinum strips of the Knudsen manometer liberate gas upon being heated which is again absorbed by them upon cooling. To investigate this the strips were heated one at a high vacuum to a red heat. The torsion balance was deflected in the direction of a stream of gas flowing from the manometer to the carbon. The pressure measured after the strips were cooled was, however, no lower than before they were heated. This work must be continued in order to furnish an answer to the questions arising regarding the condition of this vacuum must await the continuation of this work—as to whether the carbon itself absorbs as many gas molecules per unit of time as it emits, whether a constant stream of gas molecules which may be liberated from the walls is absorbed in the carbon and whether the remnants of gas consist essentially of heavy molecules (sealing wax and grease vapors) or of hydrogen and helium. Also we have not investigated whether a considerably higher vacuum can be obtained by heating the glass tubes and avoiding soldered joints. The manometer could readily be made 100 times more sensitive by using a much finer suspension.

2. If now the Wehnelt cathode was heated the pressure (especially with fresh oxide coatings) was raised in the first minute so greatly that the spot of light [20] of the manometer was moved over the entire scale scarcely one-half a second after the circuit of the cathode heating current was closed. The torsion balance was also set in vibration, but after a few minutes came to rest at its former zero point. But it was scarcely possible with the cathode glowing to obtain better vacua than about 4×10^{-5} mm. of mercury, especially when cathode rays were emitted. It is to be noted, however, that at such low pressures current intensities of about 0.1 milliampere passed through the tube.

In his most recent work Fredenhagen[21] has expressed the view that in the case of the Wehnelt cathode the surrounding gas is essential in producing discharge. In fact, I at one time observed a considerable increase of the intensity of the cathode rays as the gas pressure was raised; this is given in the following table:

Pressure	4.2	16.0	17.0	17.6	19.0	20.0	21.0×10^{-5} mm. Hg.
Current at the receiver	<0.15	1.5	2.0	2.4	2.6	3.4	4.4×10^{-7} Amprs.

But all later experiments to confirm this result showed, however, *that the discharge current does not vary with the pressure of the gas* (up to pressures of 4×10^{-5} mm. of mercury). The increase in the current observed could be explained on the hypothesis that the calcium oxide becomes dissociated in a high vacuum into $Ca_2 + O_2$ and emits more electrons according as it becomes regenerated with rising pressure.

3. Intense cathode rays of 20,000 volts and more velocity could be produced by the influence machine which excited an intense yellowish green florescence on the glass wall. As long as the rays were not deflected

by the magnet the torsion balance did not display the slightest deflection and the galvanometer and manometer also were at rest even when there was a violent sparking between the balls of the machine. At a higher temperature of the cathode (yellow heat) the voltage diminished very greatly, florescence ceased and the discharge space was perfectly dark. *In spite of this a cur-*
[21] *rent of 1 milliampere passed through the tube.* The pressure rose only slightly (with this current).

4. The position of the deflecting magnet was adjusted until the rays fell in the opening of the aluminum ball as much as possible without touching the edge. *The florescent spot* excited on a spot on the ball was surrounded by a diffused region due to the rays deflected from the wall of the tube. This region disappeared when diaphragm D_3 was used. In the last stage of my work, in order to find the best position for the torsion balance, I used a strip of glass coated with "Sidotblende" in place of the ball and mounted the magnet in such a way that a uniform sharply defined supply of florescence (8 mm. in diameter) appeared on this screen. The spot was located by two reading telescopes, the axes of which formed an angle with one another, and later the opening of the ball was moved to this position. With this adjustment the intensity of the reflected rays then diminished to 3.6—10%, whereas formerly they amounted frequently to 50% of the incident rays.

5. The intensity of the current conducted from the torsion balance was under the best conditions 1×10^{-5} ampere (therefore 1% of the total discharge current). We proved that the resulting charging of the torsion balance to about 0.04 volt did not produce any electrostatic attraction: A charge up to 2 volts gave a deflection on the scale of 0.4. We have taken into consideration a slight disturbance to the armored galvanometer, due to the deflecting magnet. The torsion balance was not perceptibly affected by it. On the other hand, the

torsion balance gave a small deflection to one side when the damping magnet was energized, and to the other side when it was taken out of the circuit. But the damping ratio did not have to be changed during an experiment.

6. In a poor vacuum of a few thousandths mm. Hg. the torsion balance was turned by the impact of cathode rays almost to the point of contact. At a low pressure (about 6×10^{-5} mm.) it gave a deflection which was equivalent to three or four times the pressure from the cathode rays, as soon as the image had come to rest, but instead of remaining constant at a constant radia-
[22] tion intensity it increased rapidly at first and after a few minutes more slowly. Apparently therefore the deflection was chiefly due to the radiometer effect of the receiving electrode as it becomes heated. Although by observation at two different pressures we have a means of eliminating the radiometer effect (see p. 10) yet an attempt was made to make it smaller.

The best means would have been to heat the rear side of the receiving ball a known amount. But the change aimed at would have been very difficult with the apparatus employed.

Lebedew, in his work on the pressure of light,[22] has given an ingenious suggestion for preventing radiometer disturbances. If the radiation is absorbed on the inside surface of the floor of a (nearly) closed box, the front of which is a material which does not absorb the radiation (a very thin mica foil) the molecular activity which causes the radiometer effects will take place only between the floor and the cover of the box and consequently will not set the receiving system in motion.

Of course the cathode rays—in contrast to light—are perceptibly absorbed by the very thin films. In spite of this I attempted to apply this suggestion. The opening of the ball was closed with aluminum stretched taut and 6×10^{-4} mm. in thickness, which was fastened down with water glass.

Favorable results were not obtained with this arrangement. The radiometer effect was reduced but the [23] reflection of cathode rays by the foil was no less, as Starke[23) also found with thick aluminum sheets. With slow rays produced by a high-voltage battery, it rose under certain conditions to more than 50%. Electrons are reflected even on the outermost surface film of the receiver. (In one experiment (No. 10), the *observed* pressure was 1.8×10^{-5} dynes; the *calculated* effect on the most favorable assumption that the number of reflected electrons, 50%, is to be doubled, was 2.4×10^{-5} dynes). After some experiments of this kind the aluminum foil was again removed because the action of the reflected rays can be taken into consideration only in an inaccurate manner.

Nichols and Hull[24) recommend that radiation be allowed to act only a very short time, as the radiometer effect always increased with increased duration of radiation; in other words, that the *ballistic deflection* of the torsion balance be observed. They derive the following formula for the case of radiation equal to *one-fourth the time of vibration:* the ballistic deflection, A, is

$$A = \frac{L}{\Phi} \sqrt{1 + r + \frac{2}{\pi} \sqrt{r} \log \frac{1}{r}} \qquad (4)$$

in which L is the moment of torsion of the radiation pressure, Φ the moment of the suspension wire, and r the radio of two constructive amplitudes. If the oscillations are practically undamped ($r = 1$), the ballistic deflection, A, is $\sqrt{2}$ times the static deflection.

This method was used for the ensuing cathode-rays experiments. The time of vibration of the torsion balance was 42.3 sec., and the length of exposure 10.6. The $\sqrt{}$ was found to be 1.885, corresponding to the ratio:

$$r = \frac{A_2}{A_1} = 0.796$$

For the heating the carbon preliminary to experiment, the electric furnace which had been used for a year became useless on account of the destruction of the asbestos insulation. After it had been rewound, the temperature it gave was found to be lower than previously. The carbon was therefore heated in this case for about eight [24] hours, until the front vacuum of the Gaede pump, which was in constant operation, displayed no further increase in pressure. But in the concluding experiments the vacuum was substantially poorer, contrary to expectation, than in all the former ones. Attempts to bring it to its former value by means of the "Vorkohle" or the Gaede pump, were unsuccessful, because the carbon acted like a large reservoir of air and besides the newly made cathode evolved much gas. The reflection of the rays was also greater as in many earlier experiments: at 3,000 volts about ⅕ of the rays were reflected, and at 15,000-20,000 volts about $\frac{1}{20}$.

Although the experiments had to be stopped for other reasons we made a series of measurements which are contained in the following table. However, owing to the relatively high pressure we did not proceed on the principle of determining the radiation pressure in an absolute vacuum by observations at two different gas pressures.

In the first column of the table is the number of the experiment, in the second the potential accelerating the cathode rays, and in the third the intensity of the current from the receiver. Then follows the ballistic deflection of the torsion balance and the pressure calculated from this. Then the pressure of the rays calculated from the current intensity and voltage (assuming that the reflected fifth (experiments 12-28) or twentieth (32-38) of the cathode rays are to be counted double). In the next to the last column is the quotient of the observed to the calculated pressure effect, and in the last column the gas pressure.

A study of the tables shows that the observed effect is always considerably higher owing to radiometer action than the calculated effect so that there can not possibly be any question of a "measurement" of the pressure of the cathode rays. (At any rate Starke found the ratio of observed to calculated cathode ray effect to be about 50 when he used the most favorable disk arrangement, while we found it to vary from 3 to 12). It is [25] also observed that the ratio increased with increasing pressure—as would be expected.

Assuming that the cathode-ray pressure has the value required by the theory and that the radiometer [26] effect is proportional to the pressure 25) we may find by calculation from the values in the table that the radiometer action at a mercury pressure of 4×10^{-5} mm.

(at which we had observed intense cathode rays) amounts to about ⅗ of the cathode ray effect and at 5×10^{-6} mm. Hg. to $\frac{1}{20}$. Accordingly, we would have to calculate accurately up to within a few per cent the cathode-ray effect which is free from radiometric disturbances at these pressures. Next to these disturbances the reflection of the rays is most difficult to avoid and to take into account. Other sources of error, such as possible inaccuracy in the energy equation, the divergence of the cathode rays, and the retardation of the electrons by the gas residue, have little importance in comparison with this.

To conclude from these investigations,—the method described offers a possible means of measuring up to within a few per cent the pressures of cathode rays, but it does not appear probable that measurements can be made of sufficient accuracy to determine from the same data the value of ε/μ or to make a decision between the relative and absolute theory. As a side issue it is found that it is possible to maintain a vacuum of 8×10^{-7} mm. Hg. by means of charcoal in a Dewar flask containing liquid air, and to measure the vacuum by a Knudsen manometer and that with a Wehnelt cathode in action a vacuum of 4×10^{-5} mm. Hg. can be maintained.

JOHN H. CLOUGH, OF SCHENECTADY, NEW YORK, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

INCLOSED-ARC DEVICE.

1,246,054. Specification of Letters Patent. Patented Nov. 13, 1917.

Application filed October 20, 1915. Serial No. 56,902.

To all whom it may concern:

Be it known that I, John H. Clough, a citizen of the United States, residing at Schenectady, in the county of Schenectady, State of New York, have invented certain new and useful Improvements in Inclosed-Arc Devices, of which the following is a specification.

The present invention relates to inclosed arc devices having a cathode consisting of highly refractory material, operating at incandescence in a gaseous atmosphere.

Formerly in arc devices of this type the anode has been constituted of either a refractory material, such, for example, as tungsten, carbon, tantalum or the like, or of mercury.

I have discovered that when the anode is constituted in part or entirely of a highly chemically reactive metal such, for example, as calcium, magnesium or titanium, the gaseous atmosphere surrounding the arc consists of a monatomic gas such as argon, neon, xenon, krypton, helium or the like, that a voltage drop in the arc of a hitherto unattainable low value is obtained.

My improvement will be more fully understood and appreciated by reference to the following description of several specific embodiments of my invention.

In connection with this description I have shown diagrammatically in Figure 1 of the accompanying drawing an incandescent cathode rectifier, as illustrating one form of apparatus to which my invention is applicable, and Fig. 2 illustrates by curves the improvement in the voltage characteristic on an arc in a device embodying my invention.

The device comprises an envelop 1 consisting of glass, such as low expansion or sodium-magnesium boro-silicate glass. The cathode 2 consists of highly refractory material, such for example, as tungsten, tantalum, carbon or the like.

The anode 3 comprises metallic calcium, magnesium, titanium or other metal highly reactive chemically to gases other than the inert so-called rare or monatomic gases. The cathode current supply wires 4, 5 and the anode conductor 6 are sealed into the stems 7, 8 in the usual manner. The cathode is preferably provided with a tip 9 having a somewhat greater diameter than the adjoining sections as described and claimed in a co-pending application filed on September 20, 1915, by Charles V. Ferguson, Serial No. 51,661.

The globe is first evacuated and then filled with a monatomic gas at considerable pressure. The action of the anode material makes it unnecessary to use such great care in exhaust as has been necessary formerly. The pressure will vary with the nature of the device and the service required of it. I may say that it should be above a pressure of several millimeters of mercury and will more usually approach the order of magnitude of atmospheric pressure.

When arc devices such as described above are operated in series with an external resistance or load, part of the impressed voltage is consumed in the arc itself, known ordinarily as the arc drop. This voltage drop is in the neighborhood of about twenty volts in a device such as described above when the anode or anodes consist of a metal such, for example, as tungsten, which is not highly chemically reactive with respect to impurities in the atmosphere of inert gas. In a device provided in accordance with my invention with an anode consisting wholly or in part of calcium or other highly chemically active metal, the arc voltage drop is as low as about four to five volts.

In the former type of device at the beginning of the half wave of current which is negative with respect to the cathode, the voltage must rise to a value about double or more the value required to maintain the arc before the arc will start and current begin to be transmitted. As soon as the arc starts the voltage quickly drops to a lower value and then remains nearly steady until near the end of the half wave when the arc again goes out as the voltage approaches the zero value. This condition is illustrated in the curve 10, Fig. 2. In my improved device the voltage at the beginning of the wave during which the arc is operating does not rise to a value higher than the operating voltage of the arc. This result as far as I am aware is entirely new. As illustrated by the curve 11, the voltage wave rises from zero to a value high enough to operate an arc, then as the arc starts the voltage drops to a slightly lower value for an instant and again rises to approximately the value at which the arc started and after rising slightly falls to zero while the current as shown in curve 12 rises from zero to a maximum value and falls again to zero. The high initial voltage peak observable in curve 10 is lacking.

The improvement effected by my invention may be illustrated by the following specific example. Argon was introduced into a device, such as above described, at a pressure of about 5 to 12 c. m. of mercury. An eight ampere arc was produced in the device with the cathode at bright incandescence having an arc voltage drop of 10.4 volts. After three hours with a calcium anode the voltage drop had decreased to 7.8 volts. With a twenty ampere arc an initial arc drop of 6.9 volts was observed which in three hours of operation had decreased to 4.5 volts. In a neon atmosphere of about ½ atmospheric pressure, purified by the usual chemical methods, a ten ampere arc was found initially to have a voltage drop of about 58 volts. The chemical effect of a calcium anode reduced the voltage drop to about 12.5 volts in about forty minutes.

Another advantage gained by the use of electrodes of highly reactive metal is the remarkably low voltage required to start the arc. For example, a fifteen ampere arc may be started with a potential as low as 14 volts with the cathode at a temperature of 2500° C.

What I claim as new and desire to secure by Letters Patent of the United States, is:—

1. The combination of a sealed envelop, a cathode of highly refractory material proportioned to operate at incandescence, an anode consisting in part at least of highly chemically active metal and a filling of rare gas having a pressure high enough to substantially prevent electrical disintegration of said cathode by an arc.

2. The combination of a sealed envelop, an incandescent cathode, an anode consisting of alkaline earth metal, and a filling of argon at a pressure exceeding several millimeters of mercury.

3. The combination of a sealed envelop, an incandescent cathode, an anode consisting of calcium, and a filling of argon.

4. The combination of a sealed envelop, a cathode of tungsten proportioned to operate at incandescence, an anode formed in part at least of metallic calcium and a filling of gas of the argon group at a pressure exceeding several millimeters of mercury.

5. The combination of a sealed envelop, a cathode of tungsten proportioned to operate at incandescence, an anode consisting in part at least of a highly chemically active metal and a filling of argon gas at a pressure of about 5 to 12 centimeters of mercury.

In witness whereof, I have hereunto set my hand this 29th day of October, 1915.

JOHN H. CLOUGH.

UNITED STATES PATENT OFFICE.

GEORGE M. J. MACKAY, OF SCHENECTADY, NEW YORK, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

INCLOSED-ARC DEVICE AND METHOD OF OPERATING THE SAME.

1,208,597. Specification of Letters Patent. Patented Dec. 12, 1916.

Application filed October 20, 1915. Serial No. 56,897.

To all whom it may concern:

Be it known that I, GEORGE M. J. MACKAY, a subject of the King of Great Britain, residing at Schenectady, county of Schenectady, State of New York, have invented certain new and useful Improvements in Inclosed-Arc Devices and Methods of Operating the Same, of which the following is a specification.

The present invention relates to inclosed arc devices having a cathode consisting of highly refractory material operating at incandescence in a gaseous atmosphere.

I have discovered that a markedly lowered voltage drop or loss in the arc is secured in a device of this type containing gases protecting the electrodes from chemical deterioration and electrical disintegration when there is provided within the device a material as, for example, calcium and related alkaline-earth metals, magnesium, or non-metallic absorbents, such as phosphorous pentoxid, which, while having no affinity for the gaseous filling, is chemically active with respect to impurities in the gaseous filling, to produce compounds of negligibly low vapor pressure with the gaseous impurities. In the case of a filling of argon, the most deleterious of the gaseous impurities tending to increase the drop of potential in the arc appear to be water vapor, hydrogen and nitrogen.

My improvement will be more fully understood and appreciated by reference to the following description of several specific embodiments of my invention.

In connection with this description, I have shown diagrammatically in the accompanying drawing in Figure 1 by way of example, a device containing an incandescent cathode, upon which the material to be vaporized is applied and in Fig. 2 a device provided with a capsule containing the material to be vaporized. Fig. 3 shows a detail of a modification.

The device comprises an envelop 1 consisting of glass, such as low expansion or sodium-magnesium boro-silicate glass. The cathode 2 consists of highly refractory material having a melting point exceeding at least about 3000° C., such for example, as tungsten, tantalum, carbon or the like. The anode 3 consists of conductive material, for example, tungsten, carbon or other solids, but in some cases, a liquid such as mercury may be used, as indicated by anode 3′ in Fig. 3. The cathode current-supply wires 4, 5 and the anode conductor 6 are sealed respectively into the stems 7, 8 in the usual manner.

The globe is first evacuated and then filled with a suitable gas at considerable pressure. Removal of water vapor from the bulb by heating the bulb during evacuation is desirable but not so necessary as when no chemical addition is used in accordance with my invention. Various gases may be used depending on the character of the service required of the device. The monatomic gases of the argon group, also nitrogen, and carbon monoxid, have been used.

The gaseous pressure also will vary with the nature of the device. I may say that it should be above a pressure of several millimeters of mercury and will more usually approach atmospheric pressure in order of magnitude. In a device used for rectifying alternating current at low voltages, argon at a pressure of about 5 to 12 c. m. of mercury is found suitable.

The material chemically active with respect to deleterious gaseous impurities in the gas filling, or deleterious gases contained in the electrodes and the glass, may be vaporized by the cathode when heated to incandescence by passage of current, or may be simply placed in the globe in any convenient manner. Metallic calcium or magnesium may, for example, be introduced as a small strip of foil or wire 9 placed upon or wrapped about one of the cathode conductors and in proximity to the cathode so as to be vaporized by the heat of the arc or by the incandescent cathode. As shown in Fig. 2, the chemical addition may be placed in a small glass capsule 10 located in an open-ended tube 11. The tip of the capsule may be broken by shaking after the evacuation of the container is complete.

In devices containing a filling of nitrogen, phosphorous pentoxid is preferred for cleaning up water vapor and other gaseous impurities. In devices filled with a monatomic gas, such as argon, neon, krypton, xenon, or helium, I prefer to use calcium, magnesium or one of the related metals. Calcium vapor will absorb all gases except the very inert monatomic gases although phosphorous pentoxid may be also used with good results for purifying monatomic gases *in situ.* Solid phosphorous pentoxid, P_2O_5, in an argon-filled device will remove hydrogen, water vapor and apparently also nitrogen to some extent. Some of the pentoxid is reduced by the hydrogen, forming water vapor which is in turn absorbed by the remaining pentoxid to form a gummy phosphoric acid of very low vapor pressure.

The beneficial effect of the purifying agents used in accordance with my invention should not be confused with the chemical purification of the gases prior to their introduction into the envelop. The chemical agent placed in contact with the atmosphere within the arc device in addition to purifying the gas filling at the beginning of the operation of the device, acts continuously to remove traces of deleterious gas given off during its operation from the electrodes, and the glass envelop. Apparently the arc activates the gaseous impurities so that they combine more readily with the chemical agents within the bulb.

By the use of a gas-absorbing chemical agent in accordance with my invention, the potential drop, or loss in an incandescent cathode device is reduced to one-half, and in many cases even to less than one-half of the drop heretofore occurring in devices filled with the above mentioned gases purified most carefully only by known chemical methods upon their introduction into the device, thereby making in some cases a device efficient enough to be usable for commercial uses from which it would otherwise be excluded.

To give specific illustrations, I may state that an incandescent cathode device carrying about six amperes when filled with argon purified by ordinary methods has an arc drop of about 30 to 40 volts. When the envelop contains a small quantity of phosphorous pentoxid, as above described, the arc drop is reduced to about ten volts. Similarly a six ampere neon tube containing, at a pressure of about half an atmosphere, neon gas purified by the usual methods has an arc drop of about 50 volts. The same tube when provided with metallic calcium acting to purify the gas *in situ* in the manner above described has an arc drop of about 20 volts.

What I claim as new and desire to secure by Letters Patent of the United States, is:—

1. The combination of a sealed envelop, arcing electrodes therein, one of which is adapted to operate at incandescence, an atmosphere of gas chemically inert with respect to said electrodes and a material chemically active with respect to impurities in said gas acting to continuously combine with gaseous impurities evolved from the electrodes and walls of the envelop during the operation of an arc between said electrodes.

2. The combination of a sealed envelop, a cathode of refractory material adapted to operate at incandescence, a coöperating anode, a filling of gas inert chemically with respect to said electrodes and suppressing the electrical disintegration of the cathode and a material forming compounds of negligibly low vapor pressure with gaseous impurities tending to increase the fall of potential in the arc between said electrodes.

3. An arc device comprising the combination of a sealed envelop, a cathode of material having a melting point exceeding about 2000° C., a coöperating anode, a filling of monatomic gas having at the operating temperature of the device a pressure of at least several millimeters of mercury, and a material forming under the operating conditions of the device compounds of negligibly low vapor pressure with polyatomic impurities in said gas.

4. An arc device comprising the combination of a sealed envelop, a tungsten cathode, an anode, a filling of argon at a pressure materially greater than one millimeter of mercury pressure and a quantity of material chemically active with respect to water vapor.

5. The method of purifying the gaseous atmosphere surrounding an incandescent cathode and a coöperating anode in a closed envelop which consists in liberating during the operation of the arc in contact with said atmosphere a vapor having no affinity for said gaseous atmosphere but chemically active with respect to deleterious gaseous impurities given off by the envelop and said electrodes.

6. The method of lowering the voltage drop of an arc between an incandescent cathode and an anode in an atmosphere of argon which consists in vaporizing during the operation of the arc in contact with the argon a material combining with water vapor to form solid materials of low vapor pressure.

In witness whereof, I have hereunto set my hand this 29th day of October, 1915.

TUNGSTEN AND METHOD OF MAKING THE SAME FOR USE AS FILAMENTS OF INCANDESCENT ELECTRIC LAMPS AND FOR OTHER PURPOSES.

1,082,933. Specification of Letters Patent. **Patented Dec. 30, 1913.**

Application filed June 19, 1912. Serial No. 704,[illegible]

To all whom it may concern:

Be it known that I, WILLIAM D. COOLIDGE, a citizen of the United States, residing at Schenectady, county of Schenectady, State of New York, have invented certain new and useful Improvements in Tungsten and Methods of Making the Same for Use as Filaments of Incandescent Electric Lamps and for other Purposes, of which the following is a specification.

This application is in part a continuation of my prior applicatons, Serial Number 324,335, filed July 2, 1906; Serial Number 521,220, filed October 6, 1909; Serial Number 545,974, filed February 23, 1910; and Serial Number 577,353 filed August 15, 1910.

My invention comprises a new incandescent lamp filament of drawn wire made from the metal tungsten, and a process of producing the same. I have been able to produce from this refractory, brittle, non-ductile and generally unworkable metal a wire which is tough, fibrous and elastic and of high tensile strength, and have thus been able to facilitate the manufacture and improve the quality of tungsten incandescent electric lamps.

The wire produced by my invention has found various other applications, and may be used wherever high tensile strength, freedom from corrosion, or ability to withstand high temperatures are of value. So also the new material of which the wire consists, fully worked ductile tungsten, has in other mechanical forms a wide variety of useful applications. Further, an incidental but valuable new product is found at an intermediate stage of my process, in tungsten which is wrought, but in which the working process has been interrupted before the above described properties have fully developed but at a point where desirable properties not found in any tungsten of the prior art have been developed to an amount sufficient for the purposes for which the material in question is to be used.

The metal tungsten is described in standard works on chemistry and metallurgy as obtained in the form of a steel-gray to black powder, having a fusing point of about 3200 degrees C. It is stated to be entirely non-ductile. Thus, for example, Roscoe and Schorlemmer's *Treatise on Chemistry*, vol. II, p. 1058, published in 1907, cites the work of Moissan, but states that: "The purest forms of tungsten at present obtainable are hard and brittle, and are not ductile either at ordinary temperatures or when heated." De Lodyguine's Patent No. 575,002, referring to tungsten, states (page 1) that it is "almost absolutely non-ductile" and "cannot be drawn out into wires in the manner employed in operating on ductile metals". Also, the British patent of Siemens & Halske Aktiengesellschaft, No. 5387 of 1908, and British patent of Consortium fur Elektro-Chemische Industrie of Nurnberg, Germany, No. 3938, of 1907, state that tungsten is non-ductile and cannot be drawn into wires.

Up to the time of my present invention all efforts to work the metal have failed, and no one had succeeded in modifying its characteristic hard brittle structure. Incandescent lamp filaments had been made of tungsten by means of a sintering process, that is, by pressing up tungsten powder with or without a binder into the desired shape, and then consolidating it at a high temperature by passing electric current through it. Filaments so formed have been of exceedingly low strength and very brittle.

I have discovered a process by which tungsten bodies, when prepared under certain conditions, as will be hereinafter more fully described, can be mechanically worked as by hammering, swaging, rolling and drawing, and have further discovered that when this mechanical working is carried on while the metal is heated to temperatures within certain maximum and minimum limits and is continued long enough, such bodies will be converted from their original crystalline character to a condition having all the characteristics of a ductile metal. In other words, the repeated hot working so changes the metal that it acquires tensile strength and also becomes pliable and ductile at ordinary or room temperatures, and if the mechanical working is carried sufficiently far, and under proper conditions, the tensile strength of the metal may become equal to or greater than that of the best steel. I have thus not only devised a new process by which it has become possible to work tungsten, as by hammering it or rolling it into the desired form, and by drawing it into fine strong wire, but I have also produced by the operation of this process a new product, viz: wrought tungsten, and, if the process be carried far enough, ductile tungsten, a material having properties and utilities different from those of any previously known substance. When it is desired to produce from this material an incandescent lamp filament, or any other body which in normal operation is to be operated at high tempertures, I use a special mode of preparation in order to minimize the tendency of the tungsten to revert to a brittle crystalline form. When this crystallization becomes excessive the crystals may, in the case of a filament, become so large as to extend across the entire section of the filament and thereupon the sections may move laterally upon each other and produce the condition known as "offsetting". I shall hereinafter describe more in detail the special method which I employ for minimizing the loss in ductility and for preventing this offsetting effect.

My process divides itself into two stages, first the preparation of an ingot or billet of tungsten, and second the working of the ingot, and I find that the more successfully the ingot is prepared the more quickly and readily it can be worked. Also, by using certain precautions in working I am able to handle ingots which have not been prepared in the best possible way. I have no doubt that with the progress of the art improvements will be made in my process whereby the ingot will be so prepared that its working becomes much easier than it now is, or whereby, through improvements in the working, less care and skill will be required in the preparation of the ingots. I will, however, first describe in detail a process which I have worked successfully on a large scale for the production of drawn tungsten wire of the highest quality suitable for filaments for incandescent lamps and by means of which a single tungsten wire seven miles long has been produced, and will thereafter describe certain of the numerous modifications of the process, within the scope of my invention, which may be resorted to as occasion requires.

In describing this process I will refer to the accompanying drawings in which—

Figure 1 shows a swaging machine, Figs. 2 and 3 are detailed views showing different forms of swaging dies; and Fig. 4 is a view of one form of wire-drawing apparatus, and Fig. 5 shows an electric furnace, and Fig. 6 is a view of an incandescent lamp made in accordance with my invention.

Starting with tungstic oxid (WO_3) as pure as commercially obtainable, I dissolve it in ammonia water and thus form ammonium tungstate, which is purified by crystallization over a steam bath and is then, after washing by distilled water and drying, decomposed by the application of moderate heat, say 400 to 500 degrees C. which drives off the ammonia and leaves purified tungstic oxid. The tungstic oxid thus purified is heated in a gas furnace for about five hours in a covered Hessian or Battersea crucible of the ordinary and well known type, after which step it is found to be coarser and of higher density and to contain matter, probably volatilized from the crucible, the effect of which, as will be hereinafter explained, is beneficial. The substances thus added to the oxid of tungsten, which for convenience I may designate as additions, consist largely of alumina, and silica. I have obtained best results when these additions occurred in the proportion of from 0.8 to 1.5 of one per cent.

If on analysis it is found that less than say 0.8 of one per cent. of additions is present, the operation of firing in the Hessian or Battersea crucible is repeated as many times as may be necessary, a new crucible being used each time. The material, which has somewhat melted and agglomerated into a mass, is ground after each firing.

The next operation is performed in a tube, for example of porcelain or fused quartz, having a diameter of one and one-half inches and a length of two feet. This tube is packed nearly full of tungstic oxid except that clear spaces are left at each end, and the tube is gradually raised by suitable gas burners or by electrical heating, in six or seven hours, to a temperature which may be between 900 degrees C. and 1150 degrees C. I may if preferred use the type of furnace described by Winne and Dantsizen in the *Transactions of the American Electrochemical Society*, vol. XX, 1911, pp. 289–90. Crystallinity in the metal powder is to be avoided and this result is aided by this slow raising of temperature. Pure, dry hydrogen passes through the tube during this heating operation for a period of say six to fifteen hours, and is preferably introduced through a small passage formed in the upper part of the charge next to the containing tube; which arrangement leaves a thick body of the charge to be acted upon by the hydrogen. In this operation the tungstic oxid, or as it is called the "yellow oxid," is progressively reduced to the blue oxid and then to the brown oxid and then to the pure metal. The powdered tungsten thus formed is inserted, in weighed quantities, into a steel mold and is by means of a hydraulic press pressed into sticks or rods which may for example be ¼ of an inch square and six inches long, though good results have also been obtained with octagonal rods.

The mold is of extreme strength and rigidity and is arranged to apply the pressure transversely of the stick to be formed. The powder is evenly placed in the mold so that the sticks shall be of uniform density from end to end.

When the pressure is removed the mold is split or opened and the pressed tungsten stick is gently slid on to a strip for example of molybdenum or tungsten and introduced into a tube of some such material as porcelain or alundum electrically heated by a winding of tungsten or platinum wire, in which apparatus the tungsten stick is fired in an atmosphere of hydrogen to a temperature of say 1200 degrees C., for from ten minutes to an hour, or long enough to permit the sticks to become strong, so that they may easily be handled. The molybdenum support may be withdrawn when the stick has been brought to a bright red heat.

The pressing operation which I have just described is performed with dry tungsten powder but I may if desired use a binder which must afterward be removed. If the binder is carbonaceous, the carbon may be removed by heating the sticks in moist hydrogen or if desired in hydrogen containing a small amount of air.

If the tube in which the heating or firing operation is performed is made of porcelain, I fire the stick on a "boat" of suitable material such for example as molybdenum.

The fired sticks are then placed, one at a time, in a closed treating vessel, ordinarily of copper and similar to those commonly used in sintering tungsten filaments, but larger and of more rugged construction, through which hydrogen or other reducing atmosphere is constantly passed, and an electrical current is passed through them sufficiently intense to raise them to a blinding white heat. This sinters the stick and converts it into a coherent slug of metal. While in the treating vessel the sticks are held in water-cooled spring clamps, one of which is carried by a fixed support while the lower one dips into a water cooled pool of mercury so as to adjust its position as the stick shortens up during sintering. In some cases I water cool the bottle itself, and I find it best to cover the lower edges of the bottle with a mercury seal.

I prefer with the ¼ inch rod six inches long to sinter at 1700 to 1800 amperes (alternating) for fifteen minutes, the current being gradually raised to this point in say about five minutes, and then to reduce the current by degrees until at the end of one minute or more it is cut off altogether, whereupon the rod may be withdrawn as soon as it cools sufficiently to allow the treating vessel to be opened. This slow reduction of the current is intended to prevent a sudden reduction of gas pressure in the treating or sintering vessel, which would tend to draw in air and produce an explosion. After the sintering operation, the ends of the slug held by the clamps and therefore but partially sintered, are broken off. This completes the preparation of the slug or billet.

The next step is the mechanical working, which, in the particular process I am now describing, is carried on as follows: In Fig. 1 A is a swaging machine which may be of the general type shown in United States patent to Dayton, No. 515,576, February 27, 1894. In this machine the head B is rotated and a pair of dies each like the dies shown for example in Fig. 2 or Fig. 3 are brought together and then separated several times in each revolution. The head B carries the swaging dies and their operating mechanism and through the machine extends a horizontal passage D for receiving the work as it passes through the dies. The dies C, unlike the ordinary swaging dies, have very short faces E, about equal in length to the diameter of the tungsten piece passing between them. The edges C' in the working surfaces are rounded or "backed off" to keep the die from digging into the rod. In some cases a die may be used having a peculiar form of face, shown in Fig. 3, in which the edges of the striking portion or face of the die are rounded off gradually.

In Fig. 5, F is a tube furnace of the type described in the Winne and Dantsizen article above referred to. It consists of a tube G of alundum or porcelain; a winding of wire H of platinum or preferably tungsten or molybdenum through which an electric current may be passed, and a heat insulating cover K of magnesite, fine silica or other suitable material held by a suitable shell or casing of asbestos, fire brick, sheet iron or the like. Hydrogen is passed through the tube G in any suitable way as by the pipe I. The operator grasps with a pair of tongs one of the tungsten billets or slugs and inserts it in the furnace, which is in some convenient location near the swager, and leaves it there until it attains a high temperature, say 1300 to 1700 degrees C., and at which, when the billet is removed from the furnace into the open air, it gives off a cloud of volatilized oxid of tungsten. He then takes the smoking hot billet with the tongs and quickly thrusts it as far as he can into the swaging machine and as quickly withdraws it. The swaging machine runs at high speed and care should be taken to keep the slug in rapid motion into and out of the dies so as not to cool it materially. The dies are chosen so that each shall produce only a slight decrease in the cross-section of the billet and if the billet is square it is necessary to use care in passing from the square to the circular form, which form is of course produced by the action of the dies, and ordinarily the dies should be so adjusted that several passes through different dies occur in the production of the circular form.

The billet after being inserted in the first dies is reheated in the furnace, then grasped by the other end and, without changing the dies, quickly thrust into the swaging machine, and quickly withdrawn as before. As many billets as may be ready for treatment are thus manipulated and then the dies are removed and other dies are inserted arranged to produce a somewhat smaller section, and so on.

Starting with the ¼ inch square billet, I am able with five (5) passes through the machine to obtain a circular rod of 210 mils. in diameter. From 210 mils. to 60 mils. I ordinarily proceed by ten steps. As the billet becomes longer and smaller in diameter I may use a gas furnace or heater instead of the electric furnace and a smaller size swaging machine, and the billet, which is now a wire or rod, is drawn by the action of mechanically driven feed rollers through the gas flame of a gas furnace, which is then located in front of the swager, and through the swaging dies, passing completely through the opening corresponding to D in Fig. 1, and when this arrangement is adopted only one pass is necessary with each die setting.

The swaging operation is continued, with continual reduction of the dies, until in six or seven more operations the wire has been reduced to thirty mils. diameter. The temperature to which the rod is heated, which was originally at white heat, is reduced at the diameter of about 40 mils. to a yellow red and this temperature is maintained to the end of the swaging operation; that is to say until a diameter of 30 mils. has been reached. At or by this time the material has become ductile at room temperature and can be bent and otherwise manipulated.

The wire drawing die L, Fig. 4, consists of a drilled diamond set in metal, held by supports M and heated by a number of gas jets N. The wire is pointed by dipping the end in fused potassium nitrite, as is disclosed in the Whitney Patent No. 1,008,762, and the pointed end is then inserted in the die and grasped by the clamp O, which may be heated at the point where it holds the wire by a gas jet P, or the operator may merely grasp by a pair of pliers the end of the wire where it emerges from the die and pull a few feet of it through the die and attach the end to a spool or spindle which is revolved by power. In this manner the whole length of the wire resulting from the swaged billet is drawn through the die, but before it passes through the die it should pass through a bath of a material known as aqua dag, which I understand is a deflocculated graphite suspended in water, or of oil dag, which is a similar preparation in which oil is used instead of water as a suspending medium. This is done in the manner set forth in the Dempster Patent No. 1,022,182. The die should be at a temperature of 600 to 650 degrees C. and the wire should be red hot both when going into the die and when emerging therefrom.

Further reduction is accomplished in the same way, the dies varying by one mil. steps down to 14 mils., making 16 drawing operations from 30 to 14 mils. At 14 mils. or thereabout the temperature of the dies may be reduced below a red heat, but the wire itself is run red hot through the die down to sizes approximating 3 mils.

From 14 to 5.5 mils. the dies should vary in steps of one-half of a mil., making 17 additional operations; from 5.5 mils. to 4 mils. there are five operations with steps of ¼ of a mil.; from four mils. to 2 mils. there are 0.2 of a mil. drafts; and from 2 mils. to 1.4 mils. there are six operations with steps of $\frac{1}{10}$ of a mil.; and from 1.4 mils. to 0.5 mil. there are 18 operations with one twentieth of a mil. draft.

As the wire reaches smaller sizes the method of pointing described in the Whitney patent above mentioned becomes inconvenient, and instead the wire is dipped in a strong solution of potassium cyanid, and current is passed through the wire in such a direction as to make it an anode. Of course the wire drawing may be stopped at any stage according to the size of wire desired.

The metal obtainable as the ultimate result of the operations above described is a new product differing radically from any form of tungsten heretofore obtained. Not only is it pliable and ductile at room temperature, but it is strong and tough. It is substantially non-oxidizing in moist air at ordinary temperatures and resists the action of acids to an unusual degree. Its specific gravity is higher than that of sintered tungsten and has been found in certain samples to run from 19.15 to 19.3. It has an exceedingly high tensile strength, as high in particular samples of .001″ diameter as 600,000 to 650,000 lbs. per square inch, is non-magnetic and not easily corroded, and is elastic and resilient.

The material has a wide variety of technical uses. If used for filaments of incandescent lamps, it may be mounted as described in the Feuerlein Patent, No. 819,009, April 25, 1906, as shown in Fig. 6 of the drawings hereto attached. Before this is done, however, the wire may if desired be freed from impurities on its surface in some suitable manner as by passing it through a bath of hot caustic soda and then through a suitable wiper. When run in the lamp the drawn tungsten filament made as described loses much of its strength but is then, if carefully prepared in accordance with the directions herein given, nevertheless a much stronger filament than that made by ordinary squirting processes. To guard against this loss in strength, the filament should not be run at a very high temperature in the lamp until the lamp has been sealed off from the evacuating pump.

If my new material is used as the target of an X-ray tube it gives the tube a life and constancy of vacuum far superior to that possible by the use of a target of any other known material. It presents many advantages for use as contacts for magnetos and other devices where making and breaking of a circuit occurs, and is for such purposes far preferable to platinum and other materials now in use.

For certain applications the complete working process resulting in an entirely ductile metal of great tensile strength is not required. For example, after a certain amount of rolling or swaging, depending on the amount of softness and strength which the metal should have for the purpose for which it is to be used, or without any swaging or rolling whatever if great strength is not necessary in the finished product, I can heat the metal, for example in an alundum tube furnace, and hammer it into any desired shape, shear it, or roll it into plates, and from these plates I can punch parts of any desired configuration provided that the material has been prepared in accordance with the directions above given, and that the operation, whatever it may be, is performed, except in cases where the fiber has been very thoroughly developed by long-repeated mechanical working, at a sufficiently high temperature. When I have desired to produce a number of identical pieces I have resorted to a drop-forging operation.

The metal produced even by incomplete working differs markedly from any form of tungsten heretofore known, for example, it is stronger and tougher and less liable to cracking on unequal heating and cooling. When the working is fairly complete, the crystals characteristic of sintered tungsten have been deformed, broken up and elongated to such an extent that the structure is fibrous. When the working is less complete the crystals are broken up, though to a less extent, and are deformed as by elongation or flattening, according to the nature of the working process. When, for example, the billet is hammered into a plate or sheet, the crystals are found to have become flattened.

An important point in practising the above described method of carrying out my invention is the temperature to which the metal is raised and at which the several operations are carried on. Where it is desired that the resulting metal shall have the properties of a wrought metal more or less pliable and ductile at ordinary temperatures, it is not only necessary to repeat the mechanical working a large number of times, but it is necessary to keep at all times within a certain range of temperature at least during the later stages of working. It is necessary, on the one hand, that the temperature be high enough to make it possible to mechanically work the body, but, on the other hand, too high a temperature is objectionable because if the temperature is too high a tendency appears to lose fiber already acquired and to pass to a state of brittleness from a state of ductility. The range of temperatures within which properly prepared tungsten bodies may be worked to produce ductility at room temperature in accordance with my invention varies with the particular material used, but according to my experience heating the metal to or working it at a temperature corresponding to white heat and materially in excess of about 1500° C. will tend to prevent, with any tungsten metal which I have been able to produce, the formation of fiber and will tend to destroy fiber which has been produced by previous working. On the other hand, an excessive amount of mechanical working tends to cause the bodies to become so fibrous and hard as to split up and break. I have found that this result may be obviated by carrying on the mechanical working during the early stages at such temperatures as enable the body to be worked and reduced in size but without causing any special change in the structure of the metal. These temperatures may correspond to a white heat or thereabout but should be above a temperature which I estimate at about 1500 degrees C. At the proper stages of the process the temperature is reduced to 1200 degrees C., or lower, whereupon as the mechanical working progresses the improvement in the structure of the metal begins.

The preparation of a tungsten body which is to be mechanically worked is an important feature of my invention, for it is not every tungsten body which is susceptible of mechanical working. For example, Moissan states (*Comptes Rendus*, vol. 123, pp. 13–16, 1896–7) that he obtained by heating tungstic acid and sugar carbon in a carbon crucible an ingot or melt which presented well fused superficial portions, but which was porous in its interior portions. Of this product Moissan says that when it is in a porous condition it has, like iron, the property that it may be consolidated (*la propriété de se souder à lui-même*), by hammering much below its point of fusion.

Subsequent investigators have expressed the opinion that the material which Moissan obtained was not pure tungsten, but tungsten contaminated by carbon. Certainly there is no indication that by hammering Moissan was able to do anything more than to close more or less the pores of the porous material, whatever it may have been, to which he refers; nor is there any indication that when he had gone thus far he had produced a material which could be worked.

I have found that in order that the swaging process may be carried on successfully it is necessary that the tungsten should be in a certain physical or molecular condition, such as is brought about by the treatments which I have discussed above. I find it particularly advantageous to work with tungsten powder which is coarse as distinguished from the exceedingly fine and impalpable powder such as has been used in the manufacture of lamp filaments. The operation of heating in the Battersea crucible coarsens the powder, as does also the reduction operation, particularly if it be carried on in the manner described, and if the hydrogen be passed rather slowly through the reduction furnace. While my invention has made it possible with certain precautions to work fine grained metal (especially if it contains oxids, which delay sintering), as by excessively small drafts and by surrounding the rod with a sheath or casing of some other metal, the condition of the tungsten which is characteristic of the coarse powder is one which is peculiarly adapted to the successful practice of my invention.

Though the operativeness of my invention obviously does not depend upon any theory of operation, I may state that I am at present of the opinion that the difficulty which is observed in swaging the rods pressed from the fine powder may well be due to the presence in such rods of certain impurities, probably gaseous impurities, as for example oxygen, which would probably occur as an oxid of tungsten. The atomic weight of tungsten is so high (184) that even a small percentage of oxygen will cause a very large percentage of the tungsten to exist as the oxid. It seems probable that in the sintering process the gaseous impurities are expelled more readily from the rod pressed from coarse powder, while in the case of a rod pressed from fine powder the tendency is to sinter quickly on the outside and so prevent or greatly retard the escape of impurities. This hypothesis is consistent with the fact that the smaller the rod the less the importance of using a specially prepared material.

My opinion that the coarseness of the structure has some effect on the sintering operation is confirmed by the fact that the effects characteristic of coarse grained powder are produced by any process by which a rod is formed which is coarse at the time it is exposed to the sintering operation. For example, I have produced rods from exceedingly fine tungsten powder which, after sintering, swage very well, by carrying on the baking operation in an iron tube furnace. The rods are packed in the tube in powdered silica and hydrogen is passed through the tube. The tube is heated by gas flames for 8 or 10 hours to a rather low temperature. This baking operation produces a rod of coarse grained structure, probably because of the fact that the oxid, naturally existing in considerable quantities in so fine a powder, requires prolonged heating to effect complete reduction and coarsens during this prolonged heating in the oxid stage.

It is desirable in all cases that the sintering operation should take place slowly, in order to give time for the action of the hydrogen to penetrate through the entire mass, and to facilitate the escape of impurities, as well as to prevent the center of the rod, by a too rapid increase of the heating current, from becoming much hotter than the outside and actually melting and running out.

The ultimate temperature reached in the sintering operation should be very high, a dazzling white heat probably not far from 2800° C. It is difficult to give any general rule except to state that if an insufficiently high temperature is reached the rod will break up in the swaging machine. Such a rod ordinarily shows a very finely grained fracture, while my experience is that the rods which are capable of being worked easily show a somewhat coarser and more crystalline fracture.

It is my belief that certain impurities in the sintered rod, such for example as oxygen and carbon, are highly detrimental and prevent the swaging operation from being successfully carried on. On the other hand I have stated above that certain additions are absorbed from the Hessian or Battersea crucible operation, and I find that these additions do not prevent the swaging while they exercise a highly beneficial action where the tungsten is to be exposed for long periods of time to high temperatures, particularly in the form of incandescent lamp filaments. It may be that "offsetting," a phenomenon which as above explained is characteristic of some drawn wire lamp filaments, is due to the crystallization of the metal and the segregation of impurities, whereby spots are developed at which this side lipping or offsetting occurs, and that the presence of the additions introduced from the Hessian or Battersea crucible retards or interferes with the diffusion of such impurities and thus retards crystallization. It is a fact that this treatment prevents offsetting.

I have succeeded in preventing offsetting in drawn tungsten filaments without using the Battersea crucible process by mixing with the tungsten powder certain refractory materials such as the oxids of thorium, zirconium, yttrium, erbium, didymium, or ytterbium. I have used with especial success thorium nitrate, which gives thoria when decomposed. A small amount of the above mentioned oxids, or of compounds or solutions which upon heating or other treatment will yield these oxids, may be mixed with the tungstic oxid before reduction or with the metal powder after reduction, or may even be introduced after the metal has been made into a stick, either by soaking the stick in a solution of a suitable substance or by heating the stick in the presence of a suitable material in the vaporous condition. When thorium nitrate is used, for example, I employ an amount which is equivalent to 2% or less of thoria referred to tungsten. The essential point seems to be that the material should be introduced before the tungsten is sintered. Such additions, particularly in the case of a filamentary body, may actually produce a certain amount of ductility and flexibility in the sintered filament without mechanical working. Usually, however, instead of directly adding these substances, I prefer to employ the treatment above described of simply firing the tungstic oxid in a Hessian or Battersea crucible, for this treatment is simple, successful and reliable.

While I have referred to a considerable extent to the manufacture of ductile tungsten in which so-called additions are introduced at some stage of the process in order that the resulting product may be especially valuable when used for filaments of incandescent lamps, and in connection with other uses where the metal is to be exposed for long periods of time to high temperatures, nevertheless operative and useful incandescent-lamp filaments may be made by carrying out my process as herein described, omitting the additions whether produced by direct introduction of additional material, as above described, or by the Battersea-crucible process; and where it is sought to obtain ductile tungsten for uses in which it is not likely to be exposed to high temperatures, the introduction of such additional substances may be entirely unnecessary. I do not however wish it to be understood that metal prepared with the additions can only be used in incandescent lamps and for similar purposes, as such metal can, as far as my present knowledge extends, be used for any purpose to which the ductile tungsten prepared without the use of the additions is applicable.

In connection with the swaging operation it should be noted that I have departed radically from the ordinary swaging process, in which the dies are long and the metal is held a considerable time in the machine or passed very slowly through it, so that a number of blows are struck at the same place on the metal, and a smooth surface is produced. I find it highly desirable, particularly in the earlier stages of the swaging process, to use a die with a very short working face such as I have shown in the drawings, and to pass the metal through the machine at high speed and so that it is still highly heated when it emerges from the dies. Indeed, it is best not to allow two successive blows to be struck at too closely overlapping places, because each impact of the die abstracts a certain amount of heat from the material and unless this precaution be observed there is great danger that a blow will be struck upon metal which is too cold to endure it without cracking. Preferably, then, the metal emerges from the swaging machine, not smooth, but showing every distinct blow of the hammer, and therefore with an irregular wavy surface.

The swaging operation, though the most successful at the moment, is not the only operation by which my invention can be practised. For example, I have succeeded, without any swaging operation whatever and using only wire-drawing dies, in producing perfectly ductile tungsten. In this case I have begun the operation with sintered conductors of relatively small size. For example, I have used ordinary sintered series tungsten incandescent lamp filaments of the diameter of 25 mils. Where the original body is so small in diameter it is relatively easy to expel injurious impurities in the sintering process, and the devices above described to facilitate this end, which are of importance in the case of the larger bodies which are required for economical large-scale production of lamp filaments, or for the preparation of larger articles, such as X-ray tube targets, projectiles, contacts, etc., become relatively unimportant where the original sintered body is of sufficiently small diameter. I point these filaments by the process of the Whitney Patent, No. 1,008,762, above referred to, and carefully insert the point into a die which is heated to 600 to 650° C. The pointed end is then seized with hot pliers (otherwise it would break) and the filament is then with great care and with a regular steady pull drawn through the die, the diameter of which should be not less than ½ a mil. (.0005 inch less than the maximum diameter of the filament at any point. The filament is then in a similar way drawn through a die having a diameter of ½ a mil. (.0005 inch) less than that of the first die, and so on down to 18 mils. Below this size the dies should vary in steps of one-quarter of a mil. until a size of say four mils is reached when the dies should then vary by one-eighth of a mil. or less. As the wire becomes smaller the temperature of drawing is reduced; at 18 mils. or thereabout the temperature is reduced from 600 or 650° to 500° C; at 10 mils. the temperature is reduced to 400° C. The dies are lubricated with aqua dag or oil dag, as in the wire-drawing process first described. After such a 25 mil. filament has been drawn to a diameter of 7 mils., it can, at room temperature, be bent around the finger without breaking, and will readily take a permanent set. As the tungsten is still further worked by drawing down to smaller sizes, the fibrous condition becomes more and more developed and the wire becomes more and more pliable, until, at a diameter of about 4 mils., it is in every sense ductile material, and could if desired be manipulated as any other ductile metal, and drawn through dies not heated above room temperature, though I ordinarily heat the dies during the last stages of the drawing process as well as during the first stages, since by the application of heat the drawing is rendered somewhat easier.

As a convenient means for keeping the tungsten hot during the drawing operation, I may, if desired, pass current through the material under treatment. The die and the portion of the wire which is hot may be inclosed in an evacuated space or in a hydrogen or other reducing atmosphere, although I do not find it necessary to do so. The lubricants mentioned herein themselves materially assist in protecting the wire from oxidation. So also I have succeeded in producing ductile tungsten by a rolling process. In carrying out such a process, at least until the metal has acquired a considerable amount of fiber, the rolling operation should be carried on with the metal at a high temperature, preferably between what is known as "bright red heat" and "white heat," and that the metal should retain this temperature as long as the rolls are acting upon it. Excessive temperatures, such as temperatures above 1500° C., are objectionable for the reasons and to the extent already explained. The rolls naturally abstract heat rapidly and therefore the metal should pass through the rolls at very high speed; it is also essential that the draft of the rolls should not be too great. Also, at least during the later stages of rolling, the temperature should not be higher than about 1200° C.; and preferably in the neighborhood of 1000° C. When a sufficiently fibrous condition has been obtained by rolling, the metal may be run through dies as above described, or the working may be continued exclusively by rolling.

What I claim as new and desire to secure by Letters Patent of the United States, is,—

1. The process of producing tungsten having a fibrous structure which consists in repeatedly hot working a crystalline body of tungsten until the crystalline structure is broken down and a fibrous structure developed.

2. The process which consists in agglomerating tungsten powder, sintering the body thus formed, subjecting it to repeated hot working, and continuing such hot working until the body remains ductile when cold.

3. The process of producing ductile tungsten wire which consists in forming a sintered body of tungsten, hot swaging said body repeatedly until it becomes fibrous in structure, and then further reducing it by hot drawing.

4. The process of producing ductile tungsten wire, which consists in first forming a sintered body of tungsten free from oxygen carbon and other impurities which would render the body unworkable mechanically, then hot swaging such sintered and purified body repeatedly until it becomes fibrous in structure and then further reducing it by hot drawing.

5. The process which consists in mechanically working while hot tungsten which is brittle at room temperature until it becomes pliable at room temperature.

6. The process of forming bodies of coherent homogeneous tungsten which consists in agglomerating tungsten powder, sintering the body thus formed, and then subjecting it to hot mechanical working to such an extent as to improve the internal structure and to bring the body into a shape adapted for use in the arts.

7. The method which consists in first producing a body of tungsten sintered or compacted throughout and free from such impurities as would render the body unworkable mechanically, and then hot working said body to such an extent as to deform its crystalline structure and to bring it into a shape adapted for use in the arts.

8. The method of producing pliable tungsten wire for lamp filaments, which consists in first producing a body of tungsten in a sintered state and free from oxygen carbon and other impurities which would render the body unworkable mechanically and then subjecting this sintered and purified body to mechanical working many times repeated, with gradual reduction in diameter and elongation in length.

9. The method which consists in agglomerating relatively coarse tungsten powder into a porous mass, eliminating harmful impurities and compacting the mass by a sintering operation, and then mechanically working the resulting body while hot into the desired shape.

10. The method of producing ductile tungsten which consists in sintering an agglomerated mass of tungsten particles or

powder into a dense coherent and homogeneous form in such manner as to allow elimination of harmful impurities, and then mechanically working said body until it is brought into the desired condition.

11. The process which consists in agglomerating tungsten powder, treating the body thus formed so as to eliminate any oxygen present therein and to produce therefrom a sintered body, and then hot working such sintered body.

12. The process which consists in reducing tungsten oxid to coarse tungsten powder, agglomerating said powder into a coherent porous body, heating said body to drive out impurities and sinter the body, and then subjecting the body to hot mechanical working.

13. The process which consists in firing tungsten oxid in a refractory crucible of the Hessian or Battersea type, reducing the oxid to coarse metallic powder, agglomerating the powder into a coherent body, sintering the body, and then subjecting it to hot mechanical working.

14. The process which consists in forming a body of tungsten powder containing additional material which will prevent coarse crystallization of the tungsten at high temperature, sintering the body, and then subjecting it to hot mechanical working.

15. The step in the preparation of tungsten bodies which consists in firing tungsten oxid in a refractory crucible of the Hessian or Battersea type, and subsequently reducing the oxid to metallic tungsten powder.

16. The process which consists in producing tungsten containing beneficial additions, forming it into a billet, sintering it at high temperature, and mechanically working it a great number of times at high temperature, and reducing the temperature during the working.

17. The method of producing bodies of tungsten pliable and ductile at ordinary or room temperatures from bodies of tungsten which are brittle at ordinary or room temperatures, which consists in heating said brittle bodies to a temperature sufficient to render them susceptible of mechanical working, repeatedly working the bodies while so heated, and during at least the last stages of mechanical working carrying on the working at temperatures such that the mechanical working has the effect of producing ductility in the finished product.

18. The method of producing bodies of ductile tungsten from bodies of tungsten which are non-ductile, which consists in mechanically working the non-ductile bodies of tungsten within a temperature range at the lower limit of which the body to be worked is soft enough to be susceptible of such working while the upper limit, at least during the later stages of the working, is sufficiently low to cause the body thus worked to retain to a greater or less degree the effect of the mechanical working.

19. The method of producing ductile tungsten which consists in repeatedly hot working a tungsten body within a range of temperature in which the body is sufficiently soft to be susceptible of such working, but maintaining the temperatures below those at which the effect of the mechanical working is lost.

20. The method of producing a body of ductile tungsten from a body of tungsten which is brittle when cold, which consists in mechanically working said body while heated to a temperature at which the body is softened and finishing the mechanical working at temperatures below those at which no ductility is imparted to the metal by the mechanical working.

21. The method which consists in mechanically working at a temperature above approximately 1500 degrees C. a tungsten body which is brittle cold, interrupting the operation before the body is brought into the form ultimately desired, and completing the mechanical working at a temperature below 1500 degrees C.

22. The method of securing a ductile metal body without previous melting of the metal, which consists in producing a compact body of metal from divided metalliferous material, consolidating said body by heating to a temperature less than the melting temperature and such as to produce a body of metal non-ductile when cold, subjecting the body to repeated mechanical working while in a heated condition, and continuing the working until the body is ductile without the application of heat.

23. The method of securing a ductile metal body without previous melting of the metal, which consists in producing from divided metalliferous material a compact body of metal, sintering said body and thereby producing a crystalline body brittle at room temperatures, and then subjecting the body to repeated mechanical working while hot, and continuing the working until the metal remains ductile when cooled.

24. A wire formed of ductile tungsten.

25. An incandescent electric lamp having a filament of drawn tungsten wire.

26. Substantially pure tungsten having ductility and high tensile strength.

27. A ductile tungsten wire having a fibrous structure.

28. A form of tungsten metal pliable at room temperature.

29. An incandescent electric lamp having a filament formed of ductile tungsten.

30. A lamp filament of tungsten which

resists offsetting and has high tensile strength.

31. A filamentary conductor of drawn tungsten so constituted as to be free from offsetting when operated as a filament of an incandescent lamp.

32. A filament for electric incandescent lamps consisting of tungsten wire which is pliable at ordinary or room temperature.

33. The material wrought tungsten, having a specific gravity of approximately 19 or greater, and capable of being forged and worked.

34. Wrought tungsten, a solid coherent material characterized by the presence of crystals deformed by mechanical working.

In witness whereof, I have hereunto set my hand this 19th day of June, 1912.

Letters Patent

IN FAVOUR OF

IRVING LANGMUIR

George the Fifth, by the Grace of God, of the United Kingdom of Great Britain and Ireland and of the British Dominions beyond the Seas King, Defender of the Faith, Emperor of India: To all to whom these presents shall come, Greeting:

Whereas IRVING LANGMUIR, of the General Electric Company, Schenectady, County of Schenectady, State of New York, United States of America, Electrical Engineer.

hath declared that he is in possession of an invention for

"Improvements in electrical discharge apparatus."

that he claims to be the true and first inventor thereof, and that the same is not in use by any other person to the best of his knowledge and belief; And whereas the said inventor hath humbly prayed that a patent might be granted unto him for the sole use and advantage of his said invention;

And whereas the said inventor (hereinafter, together with his executors, administrators, and assigns, or any of them, referred to as "the said Patentee") hath by and in his complete specification particularly described the nature of his invention: And whereas We, being willing to encourage all inventions which may be for the public good, are graciously pleased to condescend to his request: Know ye, therefore, that We, of our especial grace, certain knowledge, and mere motion, do by these presents, for us, our heirs and successors, give and grant unto the said Patentee our especial license, full power, sole privilege, and authority that the said Patentee, by himself, his agents, or licensees, and no others, may at all times hereafter during the term of years herein mentioned make, use, exercise, and vend the said invention within New Zealand and its dependencies, in such manner as to him or them may seem meet, and that the said Patentee shall have and enjoy the whole profit and advantage from time to time accruing by reason of the said invention during the term of ~~sixteen~~ fourteen years from the date hereunder written of these presents: and to the end that the said Patentee may have and enjoy the sole use and exercise and the full benefit of the said invention, We do by these presents, for us, our heirs, and successors, strictly command all our subjects whatsoever within New Zealand and its dependencies that they do not at any time during the continuance of the said term of ~~sixteen~~ fourteen years either directly or indirectly make use of or put in practice the said invention, or any part of the same, nor in anywise imitate the same, nor make or cause to be made any addition thereto or subtraction therefrom, whereby to pretend themselves the inventors thereof, without the consent, license, or agreement of the said Patentee in writing under his hand and seal, on pain of incurring such penalties as may be justly inflicted on such offenders for their contempt of this our Royal command, and of being answerable to the Patentee according to law for his damages thereby occasioned:

Provided always that these Letters Patent shall be revocable on any of the grounds from time to time by law prescribed as grounds for revoking Letters Patent granted by us, and the same may be revoked and made void accordingly: Provided also that if the said Patentee shall not pay all fees by law required to be paid in respect of the grant of these Letters Patent, or in respect of any matter relating thereto, at the time or times and in manner for the time being by law provided, and also if the said Patentee shall not supply or cause to be supplied for our service all such articles of the said invention as may be required by the officers or commissioners administering any department of our service, in such manner, at such times, and at and upon such reasonable prices and terms as shall be settled in manner for the time being by law provided, then and in any of the said cases these our Letters Patent, and all privileges and advantages whatever hereby granted, shall determine and become void, notwithstanding anything hereinbefore contained: Provided also that nothing herein contained shall prevent the granting of licenses in such manner and for such considerations as they may by law be granted: And, lastly, We do by these presents, for us, our heirs and successors, grant unto the said Patentee that these our Letters Patent shall be construed in the most beneficial sense for the advantage of the said Patentee.

In witness whereof we have caused these our Letters to be made Patent, and to be sealed as of the third day of November, one thousand nine hundred and fourteen

THE PATENTS, DESIGNS, AND TRADE-MARKS ACT, 1911.-

COMPLETE SPECIFICATION.

"Improvements in electrical discharge apparatus."

I, IRVING LANGMUIR, of the General Electric Company Schenectady, County of Schenectady, State of New York, United States of America, Electrical Engineer, hereby declare the nature of this invention and in what manner the same is to be performed, to be particularly described and ascertained in and by the following statement:-

The present invention relates to electrical vacuum discharge devices and it comprises devices in which the electrical current is carried by negative charges called electrons, emanating from the cathode, independently of gaseous ionization such as occurring, for example, in the ordinary Roentgen tube.

My present invention comprises improvements in electron discharge apparatus having a high load capacity and operable with the highest voltages. The novel features of my invention will be pointed out with greater particularity in the appended claims.

In the accompanying drawings various forms of apparatus are shown illustrative of my invention.

Fig. 1 illustrates an electron discharge tube with its parts assembled.

Figs. 2 to 5, inclusive, show alternative forms of electrode and grid constructions, and

Fig. 6 is a diagram of an electrical system illustrating one application of my electron discharge tubes.

In order to distinguish electron discharge devices made in accordance with my invention from the prior art, I will explain briefly the character of a pure electron discharge as distinguished from a discharge through ionized gas. In a Geissler tube, and a Roentgen or Crookes tube the conduction of current is accompanied by and depends upon gas ionization. Without a certain minimum amount of gas an ordinary X-ray tube ceases to operate and as this minimum is approached the resistance of the tube steadily increases.

Scientific research has shown that under certain very carefully controlled conditions with extremely low current values of the order of magnitude of .01 of one milliampere or lower and at low voltages, well below 100 volts, an electrical discharge current may take place in an evacuated space between a heated cathode and a co-operating anode without causing the residual gas to take part in the conduction of current. This effect also takes place in a vacuum when an unheated electrode consisting of certain materials, for example, potassium, is subjected to the influence of light, particularly to ultra-violet rays. The discharge current is carried by negative charges called electrons, which pass through the vacuous space under the influence of the impressed voltage. In the presence of gas these electrons, when moving with proper velocity, collide with gas molecules and give rise to gas ionization which completely changes the phenomena accompanying the discharge. The gas molecules are split up into electrons and larger and more slowly moving positive ions. The positive ions take part in the conduction of current, giving at first erratic readings on measuring instruments connected in circuit. As gas ionization continues at higher voltages a blue glow may appear. The cathode under these conditions is electrically disintegrated, technically is "Sputtered", which causes its rapid destruction. The bombardment of the cathode by positive ions also causes heating of the cathode.

The phenomena above described as being characteristic of devices involving gas ionization are taken advantage of in an incandescent cathode device known as the "Audion".

This device has been used as a receiver for radiotelegraphy and depends in its operation upon the rapid change of the discharge current when gas ionization begins. This point depends upon various accidental conditions which cause such irregularities in the operation of various devices apparently identical that sometimes only one of a considerable number can be used. Ordinarily the gas ionization in the Audion begins somewhere between 20 and 30 volts. No prior hot- cathode devices are known to me operating with currents as great as about 5 milliamperes with voltages as high as about 200 volts.

In devices made in accordance with my invention, gas ionization is either entirely absent or is negligible and a discharge takes place which is distinct in its characteristics from the described discharge taking place in an ionized gas.

The cathode is not heated by the discharge itself. Blue glow and in fact all visible indications of a discharge are absent. Glass fluorescence is absent in a device operating with a pure electron discharge. The discharge current passing through a given space with the cathode at a sufficiently high temperature so as to give a sufficient electron emission for a given voltage varies directly with the 3/2 power of the impressed voltages. If the electron emission is not sufficient, as for example when with the cathode at a given temperature the voltage exceeds the lowest value at which all the electrons are emitted are utilized, then a further increase in voltage produces substantially no change in current. The discharge is independent of the vacuum, providing the pressure is below the minimum at which gas ionization by collison will take place. As distinguished from discharges in the presence of positive ionization, the pure electron discharge is characterised by regularity and reproducibility with given conditions.

Devices made in accordance with my invention may be used for various technical purposes, such as relaying and detecting currents, producing oscillations and rectifying alternating currents with currents thousands of times greater than the minute currents at which the devices above referred to were operable.

The gas occluded in metals and driven out by the electrons impinging thereon appears to be especially liable to ionization, as it may be observed that gas eliminated from the anode even when below the pressure permissible for residual gas produces the effects accompanying gas ionization. In fact, gas thus eliminated from the anode may not even produce a difference in the reading of a McLeod vacuum gauge and yet produce ionization effects.

I have found that deleterious gases may be removed by electron bombardment even at a low temperature, which is advantageous as the device may not be adapted to receive a high energy input, or current of sufficiently high voltage may not be available.

As shown in Fig. 1, the various parts of the apparatus may be mounted in a tube, or globe E 1 upon a pedestal 2 similar to the mount employed for incandescent lamps. The cathode construction is shown in Fig. 2. It consists of a substantially straight filament 4 consisting of highly refractory material, preferably tungsten, and provided with terminals 5,5'. The filament 4 is mounted, preferably attached to a light spring 6, between two oppositely disposed supports 7 and 8 constituting a framework, which may consist of insulating material, such as glass or quartz, but in some cases may to advantage consist of metal. Upon this framework is wound a wire 9, ordinarily called a grid. The turns of the wire are closely adjacent to each other and are also very closely adjacent to but are out of contact with the incandescent cathode. By means of this grid 9, potential may be applied to exert a static control upon the movements of the electrons. A negative potential applied on the grid reduces the flow of current from cathode to anode in proportion to the degree of negative charge. A positive grid potential assists and directs the flow of current from cathode to anode in proportion to the degree of its charge. The supporting framework for the cathode and grid is attached to a rod 10, mounted upon the stem of the tube. Adjacent to the cathode grid is the anode 11 which in the present case has been indicated as consisting of a wire strung in a zig-zag manner over hooks 12 upon fork-shaped supports 13 and 14 but it is not necessary that it should assume this particular form.

both anode and grid preferably consist of tungsten, but other gas-free refractory metals may be used. By constituting the anode a continuous conductor it can be conveniently heated by passage of current during evacuation of the device and for this purpose is attached to leading-in conductors 15, 15'. The cathode terminals 5, 5' are supplied with current through leading-in wires 16, 16'. Although it is not necessary for all purposes to provide connections for each end of the grid, it is desirable to do so when the potential applied to the grid is small, and in the case of a straight or linear cathode the potential gradient along the grid may to advantage be the same as that on the filament. In this manner the potential drop from grid to cathode is the same along its length. The grid is indicated in Fig. 1 as being attached to leading-in conductors 17, 17' at opposite ends.

In some cases it is desirable to use a V-shaped incandescing conductor for the conductor for the cathode and to attach to its bight a spring as shown at 18, 19 in Fig. 8. In this manner contact of the conductor with the grid by sagging when the metal is expanded at high temperature is prevented. In Fig. 3 a plurality of loops are used in order to increase the amount of cathode surface. The filaments are shown as connected in parallel by means of conductors 20, 20'. In some cases also it may be desirable to use a plate-shaped anode. 11^1 and 11^2 show such anodes which also preferably consist of tungsten and, if desired, may be connected electrically with each other. Current connections are made by conductors 16^2,16^3, the supports 3', 14' being merely indicated. If desired the grid may be omitted and only one cathode employed.

This construction, using plate-shaped anodes, is particularly suitable for rectifying alternating current. It is especially advantageous where currents of any considerable amount are employed.

If it is desired to rectify alternating current, the anodes may be connected to the terminals of the alternating current source which is to be rectified, such for example as the secondary winding of a transformer, which has not been shown. The direct current consumption circuit may be connected to substantially the centre point of the transformer winding and to the cathode, and the grid positively charged.

The action in this case is as follows:- When the cathode is brought to incandescence it emits electrons, which travel under the influence of the impressed electromotive force to a positive electrode. The electrons will, however, be repelled by a negative electrode. The anodes or electrode 11', 11^2 will be in turn made positive or negative and current will pass from the cathode to the positive electrode. The electrode connected to the opposite terminal of the alternating source and which will be negative would act to cut down the current passing from the cathode to the positive electrode. This effect, however, is prevented by the positively charged grid.

A rectified current will therefore be produced passing through one-half of the transformer, or alternating current source, winding and one of the ~~electrodes~~ electrodes which is positive for one-half of the alternating current wave and through the other half of the winding and the other electrode which is positive for the other half of the alternating current wave.

By a somewhat similar arrangement also if a source of direct current be connected to what I have called the direct current consumption circuit and the anodes be connected to the terminals of a winding, direct current may be converted into an alternating current which will flow in the winding. When it is desired to do this, auxiliary grids may be placed between the cathode and the anodes or electrodes. These grids may be connected to an alternating current so that they are charged alternately negatively and positively and therefore, as explained above, cause current to flow alternately from the cathode to one or the other of the electrodes in synchronism with the chargings of the auxiliary grids.

In Fig. 4 the cathode has been shown as being mounted in a frame 21, consisting of ferrochrome, tungsten, or other suitable metal upon which the wire 22 constituting the grid is wound. As the grid wire is thus wound upon a conductive frame, its turns are in parallel and electrical contact may be made directly to the frame 21 by conductor 23. The leading-in-conductors 6, 6 for the cathode are insulated from the frame by glass supports 24 as indicated.

Upon the frame 21 are placed mica sheets 25 and 26 which serve to insulate the wire 27 constituting the anode from the grid. The leading-in conductors 28, 28' to which the ends of the wires are anchored may be attached to glass beads 29 fused upon the frame 21.

In Fig. 5 not only the grid 32 is wound upon the frame 33 but also the cathode wire 34 is wound upon stout metallic conductors 35, 36, consisting preferably of tungsten. The conductors 35, 36 are attached respectively to an anchoring wire 37 and to two springs 38 and 39 serving to hold taut the turns of the tungsten wire constituting the cathode and to prevent them from coming into contact with the grid wire 32. A stranded copper conductor 40 may be used to conduct current to the cathode.

The asymetric conductivity existing between the heated and unheated electrodes of a device of the character described may be utilised for various technical purposes. Reference has already been made to the rectification of current. As shown in Fig. 6, an electron discharge tube may be used for detecting electromagnetic waves in radio-telegraphy. The grid g and heated cathode c of an electron discharge tube 41 are connected respectively to the terminals of the secondary of a transformer 42, the primary of which is included in the antenna circuit

43. The antenna is grounded through a condenser 44 in the usual manner. The cathode c is heated by a local source of energy, as battery b. A battery 45 in the grid circuit 46 has its negative terminal connected to the grid g. A condenser 47 shunts the secondary of the loosely coupled transformer 43. The inductance of the transformer and the capacity of the condenser are adjusted to make the receiving circuit resonant to the frequency of the oscillations to be received. The oscillations set up by the incoming signals are superimposed upon the negative grid potential and causes a variation of current transmitted between cathode c and anode a by a local source of energy such as a battery 48 included in the local or plate circuit 49, 50 of the discharge tube. This circuit is connected, to an ordinary telephone receiver 51, preferably shunted by means of a condenser 52, whereby the signals are detected.

For the evacuation of the device the glass walls of the tube are carefully heated to as high a temperature as the glass will stand without softening and in general the most approved methods of incandescent lamp exhaust are used. The evacuation of the tube preferably while still heated is carried out by means of a suitable evacuating means, for exampl a Gaede molecular pump, which removes vapours as well as gases. Chemical evacuating means such as electrically vaporised calcium or magnesium may also be used. Either before or during the evacuation the anodes may be heated, especially when the anodes are to be run at elevated temperature during the normal operation of the device. In this case the temperature is preferably carried close to brilliant incandescence. In the case of the structure shown in Fig. 1, the heating may take place by passing an electrical current through the wire 12. In fact, the heating may take place in a suitable vacuum furnace, the temperature preferably being raised to 2500° C or even higher. However, heat alone will not remove all the gas liberated by the electron discharge, but this gas is driven out even at ordinary temperatures by the discharge itself. The discharge appears to effect especially the surface of the metal. Heating is a valuable aid in bringing gases from the interior of the metal body into the sphere of action of the discharge but may be omitted when the devices are not heated during normal operation.

The bombardment is carried out when the evacuation has proceeded to a high degree applying a potential between the cathode 8 and the anode 12, Fig. 1, the value of which depends upon the character of the device. Care should be taken to use a voltage below that at which a blue glow appears as this indicates harmful gas ionization, and , as already pointed out, sputtering and disintegration of the cathode accompanies or closely follows the blue glow phenomenon. The pump should be constantly operated to remove the gas. After the removal of the gas thus driven out, the voltage impressed between the cathode and the anode, or anodes, as the case may be, is increased, thereby driving out more gas. This process is continued step by step with a progressively higher voltage, the final voltage depending upon the character of the apparatus. In most cases the final voltage should be materially higher than the voltage at which the device is to be used in actual service. However, in the case of devices that use exceedingly high voltages, such as 50, 000 volts or even higher, substantially all the gas may be removed from the anode without resorting to voltages higher than the normal operating voltage. In the case of a plate-shaped anode which cannot be readily heated by passage of current, the discharge voltage may be chosen great enough to convey sufficient energy to the anode to raise its temperature to redness or even higher, when the device is to be used with a discharge current adapted to heat the anodes. In the case of a device in which the anode normally operates at low temperature bombardment without heating may suffice. After the metal has been freed from occluded gas, reabsorption of gas will not take place even though it is exposed to the air or other gases. For example, anodes thus treated may be removed to other apparatus which then may be evacuated without further electron bombardment of the anode or anodes.

The evacuation of the device should be preferably carried to a pressure as low as a few hundredths of a micron, or even lower, but no definite limits can be assigned. The residual gas pressure should be below the value at which ionisation by collision will take place at the given working voltage and current, with its accompanying phenomena of blue glow, disintegration of the cathode, and so forth. When the cathode and anode are located in close proximity and the discharge confined to the region between the same, the permissible pressure is higher than when the cathode and anode are at some distance. It is also true then when the anode has been carefully freed from gas, residually free gas, even if present in a sufficient amount to cause some gas ionisation when the apparatus is first started, does little harm, as it is quickly removed by the gas clean-up effect when the device is operated.

Having now particularly described and ascertained the nature of my said invention and in what manner the same is to be performed, I declare that what I claim is:-

1. An electrical discharge device comprising a gas-tight envelope, an electron-emitting cathode, and a co-operating anode, the space in said envelope being evacuated to below the pressure at which gas ionization takes place constituting a device in which the current passed over the normal working range of voltage and temperature varies with the 3/2 power of the impressed voltage for voltages above a minimum voltage depending on the electron emission of the cathode.

2. The device as claimed in claim 1, having an incandescent cathode and a gas-free anode.

3. A high vacuum electron discharge device comprising an envelope, an incandescent cathode and an anode, the space in said envelope being evacuated to such degree that the current produces no appreciable positive ionization when the impressed voltage is as high as 200 volts.

4. The device as claimed in claims 1, 2 or 3, a rigid framework located adjacent to the anode, and a conductor constituting a grid wound back and forth on the framework and located between cathode and anode.

5. An electron discharge apparatus comprising an

evacuated envelope, a refractory conductor, connections for transmitting energy to incandesce said conductor, bars located on opposite sides of said conductor, a wire wound with closely adjacent turns on said bars to constitute a grid, but out of contact with said incandescing conductor, a second set of bars closely adjacent to the first set but insulated therefrom and a conductor constituting an anode mounted thereon in a plane substantially parallel to said grid, and leading-in conductors to said grid and anode.

6. In a device as claimed in claims 4 or 5, means for maintaining the grid at a substantially uniform positive potential.

7. In a device as claimed in claim 6, means for producing a negative charge in the vicinity of the cathode.

8. The process of removing ionizable gas from an anode of an electron discharge device which consists in subjecting said anode to prolonged electron bombardment at an impressed voltage below the value at which considerable gas ionization occurs and coincidentally removing the gas thereby disengaged.

9. The method of preparing an electrical discharge device comprising a gas-tight envelope, a cathode adapted to be heated to incandescence and a co-operating anode

which consists in removing gas as completely as possible from the envelope, impressing between the cathode while at incandescence and the anode a voltage adapted to produce an electron discharge but insufficient to produce appreciable gas ionization as indicated by a blue glow, continuing evacuation, progressively raising the discharge voltage as gas is removed, and sealing said envelope when the normal operating voltage has been exceeded.

10. In a process or method as claimed in claims 8 or 9 producing the electron bombardment with an energy input below the value necessary to appreciably heat the anode.

11. An electrical disharge apparatus operating and arranged substantially as described in reference to Figs. 1, 2, 4, 5 and 6 of the drawings.

12. An electrical discharge apparatus operating and arranged substantially as described in refermnce to Fig. 3 of the drawings.

Dated at Wellington this 3rd day of November, 1914.

Letters Patent.

No. 14,677

George the Fifth, by the Grace of God of the United Kingdom of Great Britain and Ireland and of the British Dominions beyond the Seas KING, Defender of the Faith, Emperor of India: To all to whom these Presents shall come GREETING:

Whereas GENERAL ELECTRIC COMPANY, carrying on business as Electrical Engineer, at Schenectady, State of New York, United States of America, by its duly authorised officer, Henry William Darling, Treasurer of said Company

has pursuant to the *Patents Act* 1903-1921, made application for Letters Patent of an Invention for "Improvements in and relating to Electrical Discharge Apparatus.

and has made a declaration in the prescribed form that it is the assignee of Irving Langmuir, of the General Electric Company aforesaid Electrical Engineer, the actual inventor of the said invention.

and has by a complete specification fully described and ascertained the Invention.

Now therefore we do by these Letters Patent give and grant to the said GENERAL ELECTRIC COMPANY

(hereinafter called the Patentee) our especial licence, full power, sole privilege, and authority, that the said Patentee by itself, its agents, or licensees, and no others, may at all times hereafter during the term of years herein mentioned, make, use, exercise, and vend the said Invention within the Commonwealth of Australia, in such manner as to it or them may seem meet, and that the said Patentee shall have and enjoy the whole profit and advantage from time to time accruing by reason of the said Invention, during the term of fourteen years from the date hereunder written of these presents:

Provided always that these Letters Patent are subject to the following conditions:—

(1) That these [illegible]tters Patent shall be void if it is made to appear that this grant is contrar[illegible]w, or is prejudicial or inconvenient to our subjects in general, or that the said Invention is not a new Invention, or that the Patentee is not the assignee of the said Irving Langmuir or that the said Irving Langmuir is not the actual inventor of the said invention. ; and

(2) That these Letters Patent shall cease and determine if the Patentee fails to pay the renewal fee hereunder set out on the date when it becomes due, or within such further time as may be allowed.

And we do grant unto the Patentee that these Letters Patent shall be construed in the most beneficial sense for the advantage of the Patentee.

In witness whereof we have caused these our Letters to be made patent this twenty-second day of October One thousand nine hundred and fourteen and to be sealed as of the twenty-second day of October One thousand nine hundred and fourteen

L.S.

GEORGE TOWNSEND,

COMPLETE SPECIFICATION.

"Improvements in and relating to electrical discharge apparatus."

We, General Electric Company, carrying on business as Electrical Engineers at Schenectady, State of New York, United States of America, hereby declare this invention and the manner in which it is to be performed, to be fully described and ascertained in and by the following statement:—

The present invention relates to electrical vacuum discharge devices and it comprises devices in which the electrical current is carried by negative charges called electrons, emanating from the cathode, independently of gaseous ionization such as occurring, for example, in the ordinary Roentgen tube.

Our present invention comprises improvements in electron discharge apparatus having a high load capacity and operable with the highest voltages. The novel features of our invention will be pointed out with greater particularity in the appended claims.

In the accompanying drawings various forms of apparatus are shown illustrative of our invention.

Fig. 1 illustrates an electron discharge tube with its parts assembled;

Figs. 2 to 5, inclusive, shew alternative forms of electrode and grid constructions, and

Fig. 6 is a diagram of an electrical system illustrating one application of our electron discharge tubes.

In order to distinguish electron discharge devices made in accordance with our invention from the prior art, we will explain briefly the character of a pure electron discharge as distinguished from a discharge through ionized gas. In a Geissler tube, and in a Roentgen or Crookes tube the conduction of current is accompanied by and depends upon gas ionization. Without a certain minimum amount of gas an ordinary x-ray tube ceases to operate and as this minimum is approached the resistance of the tube steadily increases.

Scientific research has shown that under certain very carefully controlled conditions with extremely low current values of the order of magnitude of .01 of one milliampere or lower and at low voltages, well below 200 volts, an electrical discharge current may take place in an evacuated space between a heated cathode and a co-operating anode without causing the residual gas to take part in the conduction of current. This effect also takes place in a vacuum when an unheated electrode consisting of certain materials, for example, postassium, is subjected to the influence of light, particularly to ultra-violet rays. The discharge current is carried by negative charges called electrons, which pass through the vacuous space under the influence of the impressed voltage. In the pressure of gas these electrons, when moving with proper velocity, collide with gas molecules and give rise to gas ionization which completely changes the phenomena accompanying the discharge. The gas molecules are split up into electrons and larger and more slowly moving positive ions. The positive ions take part in the conduction of current, giving at first erratic readings on measuring instruments connected in circuit. As gas ionization continues at higher voltages a blue glow may appear. The cathode under these conditions is electrically disintegrated, technically is "sputtered," which causes its rapid destruction. The bombardment of the cathode by positive ions also causes heating of the cathode.

The phenomena above described as being characteristic of devices involving gas ionization are taken advantage of in an incandescent cathode device known as the "Audion." This device has been used as a receiver for radio-telegraphy and depends in its operation upon the rapid change of the discharged current when gas ionization begins. This point depends upon various accidental conditions which cause such irregularities in the operation of various devices apparently identical that sometimes only one of a considerable number can be used. Ordinarily the gas ionization in the Audion begins somewhere between 20 and 30 volts. No prior hot cathode devices are known to us operating with currents as great as about 5 milliamperes with voltages as high as about 200 volts.

In devices made in accordance with our invention, gas ionization is either entirely absent or is negligible and a discharge takes place which is distinct in its characteristics from the described discharge taking place in an ionized gas.

The cathode is not heated by the discharge itself. Blue glow and in fact all visible indications of a discharge are absent. Glass fluorescence is absent in a device operating with a pure electron discharge. The discharge current passing through a given space with the cathode at a sufficiently high temperature so as to give a sufficient electron emission for a given voltage varies directly with the 3/2 power of the impressed voltages. If the electron emission is not sufficient, as for example when with the cathode at a given temperature, the voltage exceeds the lowest value at which all the electrons emitted are utilised, then a further increase in voltage produces substantially no change in current. The discharge is independent of the vacuum, providing the pressure is below the minimum at which gas ionization by collision will take place. As distinguished from discharges in the presence of positive ionization, the pure electron discharge is characterised by regularity and reproducibility with given conditions.

Devices made in accordance with our invention may be used for various technical purposes, such as relaying and detecting currents, producing oscillations and rectifying alternating currents with currents thousands of times greater than the minute currents at which the devices above referred to were operable.

The gas occluded in metals and driven out by the electrons impinging thereon appears to be especially liable to ionization, as it may be observed that gas eliminated from the anode even when below the pressure permissible for residual gas produces the effects accompanying gas ionization. In fact, gas thus eliminated from the anode may not even produce a difference in the reading of a McLeod vacuum gauge and yet produce ionization effects.

We have found that deleterious gases may be removed by electron bombardment even at a low temperature, which is advantageous as the device may not be adapted to receive a high energy input, or current of sufficiently high voltage may not be available.

As shown in Fig. 1, the various parts of the apparatus may be mounted in a tube, or globe 1, upon a pedestal 2 similar to the mount employed for incandescent lamps. The cathode construction is shown in Fig. 2. It consists of a substantially straight filament 4 consisting of highly refractory material, preferably tungsten, and provided with terminals 5, 5^1. The filament 4 is mounted, preferably attached to a light spring 6, between two oppositely disposed supports 7 and 8 constituting a framework, which may consist of insulating material, such as glass or quartz, but in some cases may to advantage consist of metal. Upon this framework is wound a wire 9, ordinarily called a grid. The turns of the wire are closely adjacent to each other and are also very closely adjacent to but are out of contact with the incandescent cathode. By means of this grid 9, potential may be applied to exert a static control upon the movements of the electrons. A negative potential applied on the grid reduces the flow of current from cathode to anode in proportion to the degree of negative charge. A positive grid potential assists and directs the flow of current from cathode to anode in proportion to the degree of its charge. The supporting framework for the cathode and grid is attached to a rod 10, mounted upon the stem of the tube. Adjacent to the cathode grid is the anode 11 which in the present case has been indicated as consisting of a wire strung in a zig-zag manner over hooks 12 upon fork-shaped supports 13 and 14 but it is not necessary that it should assume this particular form. Both anode and grid preferably consist of tungsten, but other gas-free refractory metals may be used. By constituting the anode a continuous conductor it can be conveniently heated by passage of current during evacuation of the device and for this purpose is attached to leading-in conductors 15, 15^1. The cathode terminals 5, 5^1 are supplied with current through leading-in wires 16, 16^1. Although it is not necessary for all purposes to provide connections for each end of the grid, it is desirable to do so when the potential applied to the grid is small, and in the case of a straight or linear cathode the potential gradient along the grid may to advantage be the same as that on the filament. In this manner the potential drop from grid to cathode is the same along its length. The grid is indicated in Fig. 1 as being attached to leading-in conductors 17, 17^1 at opposite ends.

In some cases it is desirable to use a V-shaped incandescing conductor for the conductor for the cathode and to attach to its bight a spring as shown at 18, 19 in Fig. 3. In this manner contact of the conductor with the grid by sagging when the metal is expanded at high temperature is prevented. In Fig. 3 a plurality of loops are used in order to increase the amount of cathode surface. The filaments are shown as connected in parallel by means of conductors 20, 20^1. In some cases also it may be desirable to use a plate-shaped anode. 11^1 and 11^2 shew such anodes which also preferably consist of tungsten and, if desired, may be connected electrically with each other. Current connections are made by conductors 16^2, 16^3, the supports 13^1, 14^1 being merely indicated. If desired the grid may be omitted and only one cathode employed.

This construction, using plate-shaped anodes, is particularly suitable for rectifying alternating current. It is especially advantageous where currents of any considerable amount are employed.

If it is desired to rectify alternating current, the anodes may be connected to the terminals of the alternating current source which is to be rectified, such for example as the secondary winding of a transformer, which has not been shewn. The direct current consumption circuit may be connected to substantially the centre point of the transformer winding and to the cathode, and the grid positively charged.

The action in this case is as follows: When the cathode is brought to incandescence it emits electrons, which travel under the influence of the impressed electromotive force to a positive electrode. The electrons will, however, be repelled by a negative electrode. The anodes or electrodes 11^1, 11^2 will be in turn made positive or negative and current will pass from the cathode to the positive electrode. The electrode connected to the opposite terminal of the alternating source and which will be negative would act to cut down the current passing from the cathode to the positive electrode. This effect, however, is prevented by the positively charged grid.

A rectified current will therefore be produced passing through one-half of the transformer, or alternating current source, winding and one of the electrodes which is positive for one-half of the alternating current wave and through the other half of the winding and the other electrode which is positive for the other half of the alternating current wave.

By a somewhat similar arrangement also if a source of direct current be connected to what we have called the direct current consumption circuit and the anodes be connected to the terminals of a winding, direct current may be converted into an alternating current which will flow in the winding. When it is desired to do this, auxiliary grids may be placed between the cathode and the anodes or electrodes. These grids may be connected to an alternating current so that they are charged alternately negatively and positively and therefore, as explained above, cause current to flow alternately from the cathode to one or the other of the electrodes in synchronism with the chargings of the auxiliary grids.

In Fig. 4 the cathode 4 has been shewn as being mounted in a frame 21, consisting of ferrochrome, tungsten, or other suitable metal upon which the wire 22 constituting the grid is wound. As the grid wire is thus wound upon a conductive frame, its turns are in parallel and electrical contact may be made directly to the frame 21 by conductor 23. The leading-in conductors 5, 6 for the cathode are insulated from the frame by glass supports 24 as indicated.

Upon the frame 21 are placed mica sheets 25 and 26 which serve to insulate the wire 27 constituting the anode from the grid. The leading-in conductors 28, 28¹ to which the ends of the wires are anchored may be attached to glass beads 29 fused upon the frame 21.

In Fig. 5 not only the grid 32 is wound upon the frame 33 but also the cathode wire 34 is wound upon stout metallic conductors 35, 36, consisting preferably of tungsten. The conductors 35, 36 are attached respectively to an anchoring wire 37 and to two springs 38 and 39 serving to hold taut the turns of the tungsten wire constituting the cathode and to prevent them from coming into contact with the grid wire 32. A stranded copper conductor 40 may be used to conduct current to the cathode.

The asymmetric conductivity existing between the heated and unheated electrodes of a device of the character described may be utilised for various technical purposes. Reference has already been made to the rectification of current. As shewn in Fig. 6, an electron discharge tube may be used for detecting electro-magnetic waves in radiotelegraphy. The grid g and heated cathode c of an electron discharge tube 41 are connected respectively to the terminals of the secondary of a transformer 42, the primary of which is included in the antenna circuit 43. The antenna is grounded through a condenser 44 in the usual manner. The cathode c is heated by a local source of energy, as battery b. A battery 45 in the grid circuit 46 has its negative terminal connected to the grid g. A condenser 47 shunts the secondary of the loosely coupled transformer 42. The inductance of the transformer and the capacity of the condenser are adjusted to make the receiving circuit resonant to the frequency of the oscillations to be received. The oscillations set up by the incoming signals are superimposed upon the negative grid potential and causes a variation of current transmitted between cathode c and anode a by a local source of energy such as a battery 48 included in the local or plate circuit 49, 50 of the discharge tube. This circuit is connected to an ordinary telephone receiver 51, preferably shunted by means of a condenser 52, whereby the signals are detected.

For the evacuation of the device the glass walls of the tube are carefully heated to as high a temperature as the glass will stand without softening and in general the most approved methods of incandescent lamp exhaust are used. The evacuation of the tube, preferably while still heated is carried out by means of a suitable evacuating means, for example a Gaede molecular pump, which removes vapours as well as gases. Chemical evacuating means such as electrically vaporised calcium or magnesium may also be used. Either before or during the evacuation the anode may be heated, especially when the anodes are to be run at elevated temperature during the normal operation of the device. In this case the temperature is preferably carried close to brilliant incandescence. In the case of the structure shown in Fig. 1, the heating may take place by passing an electrical current through the wire 12. In fact, the heating may take place in a suitable vacuum furnace, the temperature preferably being raised to 2500° C. or even higher. However, heat alone will not remove all the gas liberated by the electron discharge, but this gas is driven out even at ordinary temperatures by the discharge itself. The discharge appears to affect especially the surface of the metal. Heating is a valuable aid in bringing gases from the interior of the metal body into the sphere of action of the discharge but may be omitted when the devices are not heated during normal operation.

The bombardment is carried out when the evacuation has proceeded to a high degree applying a potential between the cathode 4 and the anode 12, Fig. 1, the value of which depends upon the character of the device. Care should be taken to use a voltage below that at which a blue glow appears as this indicates harmful gas ionization and, already pointed out, sputtering and disintegration of the cathode accompanies or closely follows the blue glow phenomenon.

The pump should be constantly operated to remove the gas. After the removal of the gas thus driven out, the voltage impressed between the cathode and the anode, or anodes, as the case may be, is increased, thereby driving out more gas. This process is continued step by step with a progressively higher voltage, the final voltage depending upon the character of the apparatus. In most cases the final voltage should be materially higher than the voltage at which the device is to be used in actual service. However, in the case of devices that use exceedingly high voltages, such as 50,000 volts or even higher, substantially all the gas may be removed from the anode without resorting to voltages higher than the normal operating voltage. In the case of a plate-shaped anode which cannot be readily heated by passage of current, the discharge voltage may be chosen great enough to convey sufficient energy to the anode to raise its temperature to redness or even higher, when the device is to be used with a discharge current adapted to heat the anodes. In the case of a device in which the anode normally operates at low temperature bombardment without heating may suffice. After the metal has been freed from occluded gas, reabsorption of gas will not take place even though it is exposed to the air or other gases. For example, anodes thus treated may be removed to other apparatus which then may be evacuated without further electron bombardment of the anode or anodes.

The evacuation of the device should be preferably carried to a pressure as low as a few hundredths of a micron, or even lower, but no definite limits can be assigned. The residual gas pressure should be below the value at which ionization by collision will take place at the given working voltage and current, with its accompanying phenomena of blue glow, disintegration of the cathode, and so forth. When the cathode and anode are located in close proximity and the discharge confined to the region between the same, the permissible pressure is higher than when the cathode and anode are at some distance. It is also true then when the anode has been carefully freed from gas, residually free gas, even if present in a sufficient amount to cause some gas ionization when the apparatus is first started, does little harm, as it is quickly removed by the gas clean-up effect when the device is operated.

Having now fully described and ascertained our said invention and the manner in which it is to be performed, we declare that what we claim is:—

1. An electrical discharge device comprising a gas-tight envelope, an electron-emitting cathode, and a co-operating anode, the space in said envelope being evacuated to below the pressure at which gas ionization takes place constituting a device in which the current passed over the normal working range of voltage and temperature varies with the 3/2 power of the impressed voltage for voltages above a minimum voltage depending on the electron emission of the cathode.

2. The device as claimed in Claim 1, having an incandescent cathode and a gas-free anode.

3. A high vacuum electron discharge device comprising an envelope, an incandescent cathode and an anode, the space in said envelope being evacuated to such degree that the current produces no appreciable positive ionization when the impressed voltage is as high as 200 volts.

4. The device as claimed in Claims 1, 2 or 3, a rigid framework located adjacent to the anode, and a conductor constituting a grid wound back and forth on the framework and located between cathode and anode.

5. An electron discharge apparatus comprising an evacuated envelope, a refractory conductor, connections for transmitting energy to incandesce said conductor, bars located on opposite sides of said conductor, a wire wound with closely adjacent turns on said bars to constitute a grid, but out of contact with said incandescing conductor, a second set of bars closely adjacent to the first set but insulated therefrom and a conductor constituting an anode mounted thereon in a plane substantially parallel to said grid, and leading-in conductors to said grid and anode.

6. In a device as claimed in Claims 4 or 5, means for maintaining the grid at a substantially uniform positive potential.

7. In a device as claimed in Claim 6, means for producing a negative charge in the vicinity of the cathode.

8. The process of removing ionizable gas from an anode of an electron discharge device which consists in subjecting said anode to prolonged electron bombardment at an impressed voltage below the value at which

considerable gas ionization occurs and coincidentally removing the gas thereby disengaged.

9. The method of preparing an electrical discharge device comprising a gas-tight envelope, a cathode adapted to be heated to incandescence and a co-operating anode which consists in removing gas as completely as possible from the envelope, impressing between the cathode while at incandescence and the anode a voltage adapted to produce an electron discharge but insufficient to produce appreciable gas ionization as indicated by a blue glow, continuing evacuation, progressively raising the discharge voltage as gas is removed, and sealing said envelope when the normal operating voltage has been exceeded.

10. In a process or method as claimed in Claims 8 or 9, producing the electron bombardment with an energy input below the value necessary to appreciably heat the anode.

11. An electrical discharge apparatus operating and arranged substantially as described in reference to Figs. 1, 2, 4, 5 and 6 of the drawings.

12. An electrical discharge apparatus operating and arranged substantially as described in reference to Fig. 3 of the drawings.

Dated this 22nd day of October, 1914.

to form silver amalgam. At room temperature one or two days are required for the amalgamation. All excess unalloyed mercury must be removed from the tube. This may conveniently be done by warming the bulb slightly and surrounding the mercury side tube in a freezing mixture, or in liquid air. The mercury side container may then be sealed off. When evacuation of the envelope has been carried to a pressure low enough to enable the pure electron discharge to take place and ionizable gas has been removed from the anode to a sufficient extent to prevent the blue-glow phenomenon which is an indication of positive gas ionization, the envelope is sealed off. A device thus prepared will operate at ordinary room temperature with a substantially pure electron discharge between anode and cathode without positive ionization, even when the impressed voltage is as high as 300 to 400 volts, or even higher. However, when the voltage between anode and cathode is within a certain range an irregularity is observed in the electron discharge current, as already described.

Agent for the Applicants.

COMPLETE SPECIFICATION.

Improvements in and relating to Electrical Vacuum Discharge Devices.

We, The British Thomson-Houston Company, Limited, of 83, Cannon Street, London, E.C., Electrical Engineers and Manufacturers, do hereby declare the nature of this invention (a communication from the General Electric Company, of Schenectady, County of Schenectady, State of New York, United States of America, Electrical Engineers) and in what manner the same is to be performed, to be particularly described and ascertained in and by the following statement:—

The present invention relates to electrical vacuum discharge devices in which the electrical current is carried by negative charges called electrons, emanating from the cathode, independently of gas ionization such as occurs, for example, in the ordinary Roentgen tube.

The present invention comprises improvements in electro-discharge apparatus having a high load capacity and operable with the highest voltages.

In order to distinguish electron discharge devices made in accordance with this invention from the prior art, the character of a pure electron discharge as distinguished from a discharge through ionized gas will be briefly described. In a Geissler tube, and in a Roentgen or Crookes tube, the conduction of current is accompanied by and depends upon gas ionization. Without a certain minimum amount of gas an ordinary X-ray tube ceases to operate and as this minimum is approached the resistance of the tube steadily increases.

Scientific research has shown that under certain very carefully controlled conditions with extremely low current values of the order of magnitude of .01 of one milliampere or lower and at low voltages, well below 200 volts, an electrical discharge current may take place in an evacuated space between a heated cathode and a co-operating anode without causing the residual gas to take part in the conduction of current. This effect also takes place in a vacuum when an unheated electrode consisting of certain materials, for example potassium, is subjected to the influence of light, particularly, to ultraviolet rays. The discharge current is carried by negative charges called electrons, which pass through the vacuous space under the influence of the impressed voltage. In the presence of gas these electrons, when moving with proper velocity, collide with gas molecules and give rise to gas ionization which completely changes the phenomena accompanying the discharge. The gas molecules are split up into electrons and larger and more slowly moving positive ions. The positive ions take part in the conduction of current, giving at first erratic readings on measuring instruments connected in circuit. As gas ionization continues at higher voltages a blue glow may appear. The cathode under these conditions is electrically disintegrated, technically is "sputtered", which causes its rapid destruction. The bombardment of the cathode by positive ions also causes heating of the cathode.

The phenomena above described as being characteristic of devices involving gas ionization are taken advantage of in an incandescent cathode device invented by Professor Fleming described in Patent No. 24,850 of 1904 and also later in a device known as the "Audion" described in Patent No. 1427 of 1908. This device has been used as a receiver for radio-telegraphy and depends for its operation upon the rapid change of the discharge current when gas ionization begins. This point depends upon various accidental conditions which cause such irregularities in the operation of various devices apparently identical that sometimes only one of a considerable number can be used. Ordinarily the gas ionization in the audion begins somewhere between 20 and 30 volts. With the exception of the X-ray tube described in Patent Application No. 14,892 of 1913, no prior devices are known to the applicants operating with currents as great as about 5 milliamperes with voltages as high as about 200 volts.

In devices made in accordance with this invention gas ionization is either entirely absent or is negligible and a discharge takes place which is distinct in its characteristics from the described discharge taking place in an ionised gas. The cathode is not heated by the discharge itself. Blue glow and in fact all visible indications of a discharge are absent. Glass fluorescence is absent in a device operating with a pure electron discharge. The discharge current passing through a given space with the cathode at a sufficiently high temperature varies directly with the $3/2$ power of the impressed voltages. The discharge is independent of the vacuum, providing the pressure is below the minimum at which gas ionization by collision will take place. As distinguished from discharges in the presence of positive ionization, the pure electron discharge is characterised by regularity and reproducibility with given conditions.

Devices made in accordance with this invention may be used for various technical purposes, such as relaying and detecting currents, producing oscillations and rectifying alternating currents with currents thousands of times greater than the minute currents at which the devices above referred to were operable.

The gas occluded in metals and driven out by the electrons impinging thereon appears to be especially liable to ionisation, as it may be observed that gas eliminated from the anode even when below the pressure permissible for residual gas produces the effects accompanying gas ionization. In fact, gas thus eliminated from the anode may not even produce a difference in the reading of a McLeod vacuum gauge and yet produce ionization effects.

The above British Patent Application No. 14,892 of 1913 describes a novel electron discharge apparatus adapted particularly for the production of X-rays which is operable with a high energy input during the evacuating process. It is found that deleterious gases may be removed by electron bombardment even at a low temperature, which is advantageous as the device may not be adapted to receive a high energy input, or current of sufficiently high voltage may not be available.

Before describing the method of preparing the new type of apparatus, the structure of the apparatus illustrated in the drawings left with the Provisional Specification will be described. In the drawings:

Fig. 1 shows one form of electron discharge tube,

Figs. 2 to 6 inclusive illustrate various forms of cathode which may be used in the tube,

Figs. 7, 8 and 9 illustrate modified forms of discharge tube.

As shown in Fig. 1, the various parts of the apparatus may be mounted in a tube, or globe 1, upon a pedestal 2, similar to the mount used in incandescent lamps. The cathode 3 is centrally located and may consist of a short straight filament not shown in Fig. 1 but indicated by the position of terminals 5, 6 and shown plainly in Fig. 3. The cathode shown in Figs. 2 and 4 consist of one or more V-shaped conductors. Either form may be used, the particular form of cathode being ordinarily determined by convenience of construction. Preferably the cathode conductor is held taut by a spring 7 to avoid contact of the cathode conductor with the grid by sagging when the metal is expanded at a high temperature. The filament 3 is mounted between two oppositely disposed supports, 9, 9^1, in this case constituting a closed loop, which may consist of insulating material, such as glass or quartz, but in some cases may to advantage consist of metal. Upon this frame-work is wound a wire 10, ordinarily called a grid. The turns of the wire are closely adjacent to each other and are also very closely adjacent to but are out of contact with the incandescent cathode. By means of this grid 10 potential may be applied to exert a static control upon the movements of the electrons. A negative potential applied on the grid reduces the flow of current from cathode to anode in proportion to the degree of negative charge. A positive grid potential assists and directs the flow of current from cathode to anode in proportion to the degree of its charge.

The supporting framework for the cathode and grid is attached to a rod 11, mounted upon the stem of the tube. Adjacent to the cathode and grid is the anode 12 which in the present case has been indicated as consisting of a wire strung in a zig-zag manner over hooks 13 upon fork shaped supports 14 and 15, but it is not necessary that it should assume this particular form. Both anode and grid preferably consist of tungsten, but other refractory metals may be used. By making the anode a continuous conductor it can be conveniently heated by the passage of current during evacuation of the device and for this purpose is attached to leading-in conductors 16 and 17. The grid is indicated in Fig. 1 as being attached to leading-in conductors 18 and 19 at opposite ends, although but one terminal is ordinarily necessary.

In some cases it is desirable to use a plate-shaped anode; Fig. 2 illustrates such an arrangement suitable particularly for rectifying alternating current. The tube itself and other extraneous parts have not been shown in Fig. 2, as they are similar to Fig. 1. The cathode construction has already been referred to and the anodes 20 and 21 also preferably consist of tungsten and may be connected electrically with each other. Current connections are made by conductors 22, 23, the supports 24, 25 being merely indicated.

For the evacuation of the device the glass walls of the tube are carefully heated to as high a temperature as the glass will stand without softening and in general the most approved methods of incandescent lamp exhaust are used. The evacuation of the tube preferably while still heated is carried out by means of a suitable evacuating means, for example, a Gaede molecular pump, which removes vapours as well as gases. Chemical evacuating means such as electrically vaporized calcium or magnesium may also be used. Either before or during the evacuation the anodes may be heated, especially when the anodes are to be run at an elevated temperature during the normal operation of the device. In this case the temperature is preferably carried to brilliant incandescence. In the case of the structure shown in Fig. 1, the heating may take place by passing an electrical current through the wire 12. In fact, the heating may take place in a suitable vacuum furnace, the temperature preferably being raised to 2500° C. or even higher. However, the heat alone, will not remove all the gas liberated by the electron discharge, but this gas is driven out even at ordinary temperatures by the discharge itself. The discharge appears to affect especially the surface of the metal. Heating is a valuable aid in bringing gases from the interior of the metal body into the sphere of action of the discharge but may be omitted when the devices are not heated during normal operation.

The bombardment is carried out when the evacuation has proceeded to a high degree by applying a potential between the cathode 3 and the anode 12, Fig. 1, the value of which depends upon the character of the device. Care should be taken to use a voltage below that at which a blue glow appears as this indicates harmful gas ionization, and, as already pointed out, sputtering and disintegration of the cathode accompanies or closely follows the blue glow phenomenon. The pump should be constantly operated to remove the gas. After the removal of the gas thus driven out the voltage impressed between the cathode and the anode, or anodes, as the case may be, is increased, thereby driving out more gas. This process is continued step by step with a progressively higher voltage, the final voltage depending upon the character of the apparatus. In most cases the final voltage should be materially higher than the voltage at which the device is to be used in actual service. However, in the case of devices that use exceedingly high voltages, such as 50,000 volts or even higher, substantially all the gas may be removed from the anode without resorting to voltages higher than the normal operating voltage. In the case of a plate shaped anode which cannot be readily heated by passage of current, the discharge voltage may be chosen great enough to convey sufficient energy to the anode to raise its temperature to redness or even higher, when the device is to be used with a discharge current adapted to heat the anodes. In the case of a device in which the anode normally operates at low temperature, bombardment without heating may suffice. After the metal has been freed from occluded gas, reabsorption of gas will not take place even though it is exposed to the air or other gases. For example anodes thus treated may be removed to other apparatus which then may be evacuated without further electron bombardment of the anode or anodes.

The evacuation of the device should be preferably carried to a pressure as low as a few hundredths of a micron, or even lower, but no definite limits can be assigned. The residual gas pressure should be below the value at which ionization by collision will take place at the given working voltage and current, with its accompanying phenomena of blue glow; disintegration of the cathode and so forth. When the cathode and anode are located in close proximity and the discharge confined to the region between the same, the permissible pressure is higher than when the cathode and anode are at some distance. It is also true that when the anode has been carefully freed from gas, residual free gas even if present in a sufficient amount to cause some gas ionization when the apparatus is first started, does little harm, and it is quickly removed by the gas clean-up effect when the device is operated.

Electron discharge apparatus thus provided with a gas-free pretreated anode or anodes may be constructed to handle currents at a very high voltage by proper mechanical design of the parts subjected to static strains, suitable proportioning of the parts and so forth.

As stated above in some cases it is desirable to use one or more V-shaped incandescing conductors for the cathode and to attach to the bights springs 7 to prevent contact of the conductor with the grid by sagging when the metal is expanded at high temperature. In Fig. 4 a plurality of loops are used in order to increase the amount of cathode surface. The filaments are connected in parallel by means of conductors 26 and 27.

In Fig. 5 the cathode 3 has been shown as being mounted in a frame 28, consisting of ferrochrome, tungsten, or other suitable metal upon which the wire 10 constituting the grid is wound. As this grid wire is thus wound upon a conductive frame its turns are in parallel and electrical contact may be made directly to the frame 28 by conductors 29. The leading-in conductors for the cathode are insulated from the frame by glass supports 30 as indicated.

Upon the frame 28 are placed mica sheets 31 and 32 which serve to insulate the wire 10 constituting the anode from the grid. The leading-in conductors to which the ends of the wires are anchored may be attached to glass beads 33 fused upon the frame 28.

In Fig. 6 not only the grid 10 is wound upon a frame but the cathode wire 3 is also wound upon stout metallic conductors 34 and 35 consisting preferably of tungsten. The conductors 34, 35 are attached respectively to an anchoring wire 36 and to two springs 37 serving to hold taut the turns of the tungsten wire constituting the cathode and to prevent them from coming into contact with the grid wire 10. A stranded copper conductor 38 may be used to conduct current to the cathode.

In the modified form of electron discharge device shown in Fig. 7, which is specially suitable for converting direct current into alternating current, the enclosing globe 1 has been shewn as partly broken away to disclose the interior arrangement of the electrodes comprising a V-shaped filamentary cathode 3, and plate-shaped anodes 20 and 21, such as illustrated in Fig. 2. Surrounding the cathode is a frame 38 of glass, upon which is wound fine wire constituting the grid 10 with closely adjacent turns surrounding the cathode 3. Located respectively between this grid and each of the anodes are grids 39 and 40, similar to those in Fig. 5, the function of which will be hereinafter explained. The cathode conductor is attached to terminal supports 41 and 42 which are in turn connected to leading-in wires 43 and 44, sealed into the stem 45 of the enclosing globe in the usual manner. The cathode filament is maintained taut by being anchored by its bight by means of the spring 7 attached to the frame 38 which together with the grid frames is carried by the pedestal 46. The anode stems 47 and 48 consist of tungsten or molybdenum and are held in position in the extensions 49 and 50 of the bulb by springs 51, which grip the walls of the bulb. Connection is made to the anodes in the usual manner by the leading in wires 52 and 53. Connection to the grid surrounding the cathode is made by leading in wires 54. The grids 39 and 40 are preferably wound upon metallic frames 31 and 32 consisting, for example, of ferrochrome which thus short circuit the turns of the grid. Electrical connection is made thereto by conductors 55 and 56.

Fig. 8 illustrates somewhat diagrammatically an electron discharge device suitable for rectifying alternating current in which a plate 57 is located between an electron-emitting cathode 58 and an anode 59. Heating current is supplied to the cathode conductor by a battery 60 and a source of energy, for example, a transformer 61, is connected between the cathode and the anode. Surrounding the cathode is a concave dished plate 62 which is maintained negatively charged, conveniently by connecting it to the cathode by means of a conductor 63. This ring serves to modify the static field so as to focus the electrons into a fairly well defined stream which passes through an aperture in the plate 57 to the anode.

By maintaining the plate 57 positively charged, for example by means of a battery 64, the passage of the electrons from the cathode to the anode is assisted. The potential of the battery 64 and hence the charge on the plate 57 may be only a fraction of the potential between supply conductors 65, 66. The electrons will be attracted to the plate 57 but will largely pass through the aperture in the same, as this represents the centre of static attraction. By making the potential of the plate 57 relatively low the loss of energy by the absorption of electrons on the part of the plate will be relatively small, and will be more than compensated by the increase in discharge current.

The rectified current may be utilised by load devices 67. If it is desired to utilise both half waves of the alternating current, two sets of devices of the type illustrated in Fig. 8 are used.

In the devices above described, the tube is exhausted to the highest possible degree of vacuum, the gas being driven out of the walls of the tube as well as out of all of the metal electrodes. Under these conditions the current flow in the tube between the incandescent cathode and the plate or anode is due to a pure electron discharge from the heated cathode and is not dependent upon the presence of residual gas as a conducting medium.

If however a certain amount of residual gas be present in the tube then the operation of the device becomes quite different. Such a construction and mode of operation is that characteristic of the "Audion". In the "Audion", if very low voltage be used in the local or plate circuit, the device is relatively very insensitive, or in other words the change of current in the local circuit is very small for a given change of potential on the grid. The device becomes more sensitive as the voltage in the local circuit is increased. There is a limit however to the voltage which may be used in the local circuit because as the voltage is increased ionisation of the gas in the tube increases, a blue glow appears followed by deterioration of the electrodes, disengagement of more gas therefrom and finally destruction of the operative qualities of the tube. The voltage impressed on the local circuit is therefore made as high as possible consistent with the avoidance of these limited conditions. In the "Audion" as thus constituted, a decrease of potential on the grid causes a decrease of current in the local circuit, while increase of potential on the grid causes an increase of current in the local circuit, but the decrease of current is of a magnitude very much greater than the increase of current caused by an increase of potential on the grid. The result is that when high frequency oscillations are impressed upon the grid their presence is made known by a decrease of current in the local or plate circuit, which decrease is detected by the telephone or other indicator placed in the local circuit.

It has been found that by maintaining within the evacuated container of a device of the general nature already described a certain definite pressure of gas, which in amount is very much less than that which is necessary to make the "Audion" operative, and not much higher than would be tolerated in a device such as described above, very remarkable results are secured in the relations which then exist between the current in the plate circuit and the changes of potential on the grid. With this definite pressure of gas or vapour in the device it is found that the variation of current in the plate circuit with variation of potential on the grid follows the law of a pure electron discharge tube such as that described above, except within a small range of voltage in the grid circuit. Within this small range there appears to be a condition of instability such that when high frequency oscillations are impressed upon the grid there always follows a sudden decrease of current in the local circuit. The explanation of this phenomenon is decidedly obscure but the existence of the phenomenon is very real. Within the range of voltage indicated, the application of high frequency oscillations or of continuous high frequency waves causes the current in the local circuit to decrease so suddenly that a very distinct signal is produced in the telephone receiver or other indicating device in the local circuit. The sharpness of the signal thus produced is such that the device illustrated in Fig. 9 is not only extremely sensitive to receive high frequency impulses but because of the sharpness of the signals the effect of "static" is not nearly so serious as in other detecting devices at present in use.

While this form of detector is dependent upon the presence of a small but definite gas pressure in the space including the electrodes, its operation is not accompanied by blue glow or any other well recognised evidences of positive gas ionization. The amount of gas or vapour present is perhaps not more than one-tenth of that which characterises the "Audion".

The sensitiveness of this device varies with the potential impressed upon the grid and becomes a maximum at a certain definite potential. To secure this maximum sensitiveness a definite potential which varies according to the particular device is impressed upon the grid circuit. As this potential is changed by the high frequency oscillations the current in the plate circuit is suddenly decreased, thereby producing the desired signal.

In producing and maintaining the desired gas pressure in this device it is not sufficient to leave in the tube a certain amount of residual gas during exhaustion since this gas does not remain constant in amount but generally will decrease upon operation of the device by the well-known clean-up action, though in some cases the amount of gas present increases rather than decreases, due to other causes. To secure the necessary definite gas or vapour pressure in the tube, a substance with the desired vapour pressure is provided and placed in the tube. Among other things it has been found that amalgam is suitable for the purpose. Mercury alone appears to be unsuitable as it has too high a vapour pressure at ordinary temperatures though by lowering the temperature of the mercury the desired vapour pressure may be obtained.

As shown in Fig. 9, the discharge device is very similar to that illustrated in Fig. 1 and comprises an enclosing envelope 1, in which are mounted an electron-emitting cathode 3 and an anode 12, both of which may, as before, consist of wire preferably of tungsten, tantalum, or other highly refractory metal. The anode need not be a wire but may be a plate properly freed from gas as described in connection with Fig. 2. The cathode 3 is a short V-shaped tungsten filament connected to terminal conductors 69, 70 and supported at its bight by a hook 68, both the supply conductors and the hook 68 being mounted on a frame 71 so that the filament is located in a plane passing through the side arms of the frame. The cathode supports 68, 69 and 70 are provided with small glass discs 72 which reduce the tendency of a short-circuit between the cathode and the grid by vaporised metal deposited on the frame 71. Around the outside of the frame is wound the grid 10 for varying the electric field near the cathode and thereby varying the electron current between the cathode and the anode. The anode wire 12 is supported by hooks 13 located upon a forked glass support 15. The frame 71 and the support 15 are mounted upon a glass stem 73 sealed into one end of the envelope. Leading-in conductors 74, 75, supply heating current to the cathode and the conductors 76, 77 are connected to the terminals of the anode and are sealed into the stem in the usual manner. The anode is provided with current connections at each terminal so as to enable it to be heated during the evacuation of the device. Only one electrical connection is made to the grid by means of conductors 78 sealed into the envelope as the grid may be sufficiently freed from gas without heating it by passage of current.

Before the envelope is sealed off there is placed in it (in a manner hereinafter described) a small amount of vaporisable material 79, for example an amalgam, sulphur, phosphorus pentoxide, tungsten hexachloride, and in general substances having a suitable vapour pressure at the operating temperature of the device. Substances having too high a vapour pressure, for example mercury, may be used if maintained during operating at a suitable low temperature, as in a side chamber. Gases at proper pressure will give the desired effect but the effective pressure, and possibly also the character of the gas are changed by some chemical or electro-chemical action in the tube so that gases act only temporarily. The material 79 is either loosely placed in the main envelope as indicated, or placed in a side chamber. The character of this material depends upon the temperature and voltages at which the device is operated, as will be hereinafter explained, its purpose being to maintain in the space vapour at a definite low pressure.

For the evacuation of the device the glass walls of the tube are heated so as to free them from moisture and both the anode and the cathode are heated by passage of current so as to drive out the gases. When an amalgam is to be used as the source of vapour, the metal to be amalgamated, for example silver, preferably is placed in the envelope before evacuation. The mercury is preferably placed in a side chamber which is kept cool during the preliminary bake-out. The evacuation of the tube is carried out, as described above with reference to the modifications illustrated in Figs. 1, 7 and 8, by the most approved methods of incandescent lamp exhaust, and the last traces of gas are removed by either a Gaede molecular pump or by some chemical evacuating means. The last traces of ionizable gases are also removed from the electrodes by heating them to incandescence and preferably at the same time operating the grid as the anode for an electron discharge, the impressed voltage being increased step by step as the gas is removed. After the parts of the device and the silver, or other metal to be amalgamated, has been freed from gas, mercury vapour is permitted to diffuse into the envelope: for example, clean mercury may be kept at a relatively low temperature in a side chamber during the exhaust. When the exhaust is completed the mercury may be permitted to reach room temperature, or even higher temperatures, thus diffusing into the main envelope to form silver amalgam. At room temperature one or two days are required for the amalgamation. All excess unalloyed mercury must be removed from the tube. This may conveniently be done by warming the bulb slightly and surrounding the mercury side tube in a freezing mixture, or in liquid air. The mercury side container may then be sealed off. When evacuation of the envelope has been carried to a pressure low enough to enable the pure electron discharge to take place and ionizable gas has been removed from the anode to a sufficient extent to prevent the blue-glow phenomenon which is an indication of positive gas ionization, the envelope is sealed off. A device thus prepared will operate at ordinary room temperature with a substantially pure electron discharge between anode and cathode without positive ionization, even when the impressed voltage is as high as 300 to 400 volts, or even higher. However, when the voltage on the grid circuit is within a certain range an irregularity is observed in the electron discharge current, as already described.

Having now particularly described and ascertained the nature of our said invention, and in what manner the same is to be performed, we declare that what we claim is:—

1. An electric vacuum discharge apparatus comprising a sealed envelope containing a cathode adapted to be heated, a cooperating anode and a conductor arranged in operative relation to the electrodes, the envelope being evacuated to such an extent that there are no visible or other indications of gas ionization when a discharge passes between the electrodes.

2. An electric vacuum discharge apparatus comprising a sealed envelope containing an electron emitting cathode and a rigid insulating framework mounted in proximity to the cathode and having a conductor wound upon a portion thereof constituting a grid and a second conductor wound upon another portion of the framework and constituting an anode, the envelope being exhausted to such an extent that there are no visible or other indications of gas ionization when a discharge passes between the electrodes.

3. In an electric vacuum discharge apparatus as claimed in Claim 1, a conductor in part at least surrounding the cathode and provided with means for maintaining it at a uniform positive potential with respect to the cathode and means for producing a negative charge in the neighbourhood of the cathode.

4. An electric vacuum discharge apparatus comprising a sealed highly evacuated envelope containing a cathode adapted to be heated, cooperating anodes located on opposite sides of the cathode, a grid connected to the positive terminal of a source of potential, surrounding the cathode in close proximity

thereto but out of contact therewith and two further grids connected to separate sources of potential arranged on opposite sides of the cathode between the first mentioned grid and the anodes.

5. An electric vacuum discharge apparatus comprising a sealed envelope evacuated to such an extent that substantially no gas ionization takes place when a discharge occurs within it, containing an electron emitting cathode and a co-operating anode, the electrons emitted from the cathode being first subjected to a static field, positive with respect to the cathode and then having their motion controlled by a field independent of the positive field.

6. In an electric vacuum discharge apparatus as claimed in Claim 1, means for maintaining within the envelope a gas at a definite pressure at which the apparatus possesses a critical region of sensitiveness to changes of the electrical field near the cathode while carrying current independently of gas conduction.

7. In an electric vacuum discharge apparatus as claimed in Claim 1, a vaporisable substance enclosed in the envelope having a vapour pressure of from about six to forty hundred thousandths of a millimeter of mercury.

8. An electric vacuum discharge apparatus comprising a sealed envelope containing a cathode adapted to be heated to incandescence, a co-operating anode, a conductor adapted to vary the electrical field near the cathode, and a vaporizable alloy such as a mercury silver amalgam, the envelope being deprived of ionizable gas to such a degree that it operates with a pure electron discharge free from positive ionization at impressed terminal potentials as high as 200 volts.

9. In an electric vacuum apparatus of the type hereinbefore described and claimed, the method of removing ionizable gas from the anode which consists in subjecting it to a prolonged electron bombardment with an energy input below the value necessary to appreciably heat the anode and at the same time removing the gas released thereby.

10. In an electric vacuum discharge apparatus of the type hereinbefore described and claimed, the method of obtaining a high vacuum which consists in evacuating the envelope to a high degree, impressing between the cathode and anode a voltage adapted to produce an electron discharge but insufficient to produce appreciable gas ionization as indicated by a blue glow at the cathode, and step by step raising the discharge voltage and continuing the evacuation until the anode will no longer disengage ionizable gas at the normal working current and voltage, and finally sealing the envelope when the normal operating voltage has been exceeded.

Dated this 1st day of February, 1915.

UNITED STATES PATENT OFFICE.

WILLIAM C. WHITE, OF SCHENECTADY, NEW YORK, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

ELECTRICAL-DISCHARGE DEVICE.

1,159,307. Specification of Letters Patent. Patented Nov. 2, 1915.

Application filed March 28, 1914. Serial No. [illegible].

To all whom it may concern:

Be it known that I, WILLIAM C. WHITE, a citizen of the United States, residing at Schenectady, in the county of Schenectady, State of New York, have invented certain new and useful Improvements in Electrical-Discharge Devices, of which the following is a specification.

My present invention comprises certain improvements in vacuum electric devices and is of particular value in connection with the detection of high frequency oscillations used in electro-magnetic wave signaling systems.

My improved detector is in construction somewhat similar to the well-known "audion" set forth in U. S. patent to De Forest #879,532, and is also similar in construction to the vacuum tube device described and claimed in an application filed by Irving Langmuir, October 16, 1913, serial No. 795,810. In both of these prior devices an exhausted glass tube is provided having a cathode adapted to be heated to incandescence by some suitable source of current, an anode or plate connected in a local circuit with one terminal or leg of the incandescent cathode, and a conductor or grid located in proximity to the cathode and upon which a varying potential is impressed, the variations of which affect the amount of current flowing in the vacuum space between the cathode and the plate or anode. The change in current in this local circuit bears no necessarily definite relation to the change of potential on the grid, but is very greatly affected by the nature of the vacuous space in which the electrodes are located. Thus, in the vacuum relay or amplifier of the type shown in the said Langmuir application, the tube is exhausted to the highest possible degree of vacuum, the gas being driven out of the walls of the tube as well as out of all of the metal electrodes. Under these conditions the current flow in the tube between the incandescent cathode and the plate or anode is due to a pure electron discharge from the heated cathode, and is not dependent upon the presence of residual gas as a conducting medium. In a tube thus highly exhausted, current in the local circuit or plate circuit increases with increase of grid potential and decreases with decrease of grid potential, but the difference in the amount of increase for a given variation of grid potential is not so far different from the decrease caused by a decrease of grid potential as to make the device a good detector of high frequency oscillations. In other words, the asymmetry of current flow in the local circuit due to a series of high frequency oscillations is not sufficiently great to enable the device to operate effectively in connection with a telephone or other receiver for detecting such high frequency impulses. The device is more especially valuable as a relay or amplifier of such oscillations. If, however, a certain amount of residual gas be present in the tube then the operation of the device becomes quite different. Such a construction and mode of operation is that characteristic of the so-called audion. In the audion, if very low voltage be used in the local or plate circuit, the device is relatively very insensitive, or in other words, the change of current in the local circuit is very small for a given change of potential on the grid. The device becomes more sensitive as the voltage in the local circuit is increased. There is a limit however to the voltage which may be used in the local circuit because as the voltage is increased, ionization of the gas in the tube increases, a blue glow appears followed by deterioration of the electrodes, disengagement of more gas therefrom and finally destruction of the operative qualities of the tube. The voltage impressed on the local circuit is therefore made as high as possible consistent with the avoidance of these limited conditions. In the audion as thus constituted, a decrease of potential on the grid causes a decrease of current in the local circuit while increase of potential on the grid causes an increase of current in the local circuit, but the decrease of current is of a magnitude very much greater than the increase of current caused by an increase of potential on the grid. The result is that when high frequency oscillations are impressed upon the grid their presence is made known by a decrease of current in the local or plate circuit, which decrease is detected by the telephone or other indicator placed in the local circuit.

I have found that by maintaining within the evacuated container of a device of the general nature already described, a certain definite pressure of gas, which in amount is very much less than that which is necessary to make the so-called audion operative, and not greatly more than would be tolerated in a device such as disclosed in the Langmuir application, very remarkable results are secured in the relations which then exist between the current in the plate circuit and the changes of potential on the grid. With this definite pressure of gas or vapor in the device, I have found that the variation of current in the plate circuit with variation of potential on the grid follows the law of a pure electron discharge tube such as that of the Langmuir application, except within a small range of voltage in the plate circuit. Within this small range there appears to be a condition of instability such that when high frequency oscillations are impressed upon the grid there always follows a sudden decrease of current in the local circuit. The explanation of this phenomenon is decidedly obscure but the existence of the phenomenon is very real. Within the range of voltage indicated, the application of high frequency oscillations or of continuous high frequency waves, causes the current in the local circuit to decrease so suddenly that a very distinct signal is produced in the telephone receiver or other indicating device in the local circuit. The sharpness of the signal thus produced is such that my improved device is not only extremely sensitive to receive high frequency impulses but because of the sharpness of the signals the effect of "static" is not nearly so serious as in other detecting devices.

While my improved detector is dependent upon the presence of a small but definite gas pressure in the space including the electrodes, its operation is not accompanied by blue glow or any other well recognized evidences of positive gas ionization. The amount of gas or vapor present is perhaps not more than [illegible] of that which characterizes the so-called audion.

The sensitiveness of my improved devices varies with the potential impressed upon the grid and becomes a maximum at a certain definite potential. To secure this maximum sensitiveness, a definite potential which varies according to the particular device is impressed upon the grid circuit. As this potential is changed by the high frequency oscillations, the current in the plate circuit is suddenly decreased, thereby producing the desired signal.

In producing and maintaining the desired gas pressure in my improved device it is not sufficient to leave in the tube a certain amount of residual gas during exhaustion since this gas does not remain constant in amount but generally will decrease upon operation of the device by the well-known clean-up action, though in some cases the amount of gas present increases rather than decreases, due to other causes. To secure the necessary definite gas or vapor pressure in the tube, I therefore provide a substance with the desired vapor pressure and place this in the tube. Among other things I have found that amalgam is suitable for the purpose. Mercury alone appears to be unsuitable, as it has too high a vapor pressure at ordinary temperatures though by lowering the temperature of the mercury the desired vapor pressure may be obtained.

The novel features of my invention are pointed out with greater particularity in the appended claims, and for a better understanding of my invention reference may be had to the following description taken in connection with the accompanying drawing in which—

Figure 1 is a perspective view of one type of apparatus embodying my invention; Fig. 2 illustrates by means of curves some of the electrical characteristics of the device; Figs. 3, 4 and 5 are diagrams of connections illustrating how the new device may be used in radio-telegraphic receiving systems.

As shown in Fig. 1 the discharge device comprises an inclosing envelop 1, which may be of glass, in which are mounted an electron-emitting cathode 2 and an anode 3. In the device illustrated both the cathode and anode consist of wire preferably of tungsten, tantalum, or other highly refractory metal which can be readily freed from ionizable gas. The anode need not be a wire but may be a plate properly freed from gas and it has been thus diagrammatically indicated in Fig. 3. The cathode 2 is a short V-shaped tungsten filament connected to terminal conductors 4, 5 and supported at its bight by a hook 6, both the supply conductors and the hooks 6 being mounted on a frame 7 so that the filament is located in a plane passing through the side arms of the frame.

The cathode supports 4, 5 and 6 are provided with small glass disks 8 which reduce the tendency of a short circuit between the cathode and the grid by vaporized metal deposited on the frame 7. Around the outside of the frame is wound a wire 9 with closely spaced turns. This conductor 9 commonly called the grid, serves the purpose of varying the electric field near the cathode and thereby varying the electron current between cathode and the anode. The anode wire is conveniently supported by hooks 10 located upon a forked glass support 11. The frame 7 and the support 11 are mounted upon a glass stem 12 sealed into one end of the envelop. Leading-in conductors 13, 13′ which supply heating current to the cathode and the conductors 14, 14′ which are connected to the terminals of the anode are sealed into the stem 12 in the usual manner. The anode is provided with current connections at each terminal so as to enable it to be heated during the evacuation of the device. But one electrical connection is made to the grid by means of conductor 16 sealed into the envelop as the grid may be sufficiently freed from gas without heating it by passage of current.

Before the envelop is sealed off there is placed in it (in a manner hereinafter described) a small amount of vaporizable material 17, for example, an amalgam, sulfur, phosphorus pentoxid, tungsten hexachlorid, and in general substances having a suitable vapor pressure at the operating temperature of the device. Substances having too high a vapor pressure, for example, mercury, may be used if maintained during operation at a suitable low temperature, as in a side chamber. Gases at proper pressure will give the desired effect but the effective pressure, and possibly also the character of the gas are changed by some chemical or electrochemical action in the tube so that gases act only temporarily. The material 17 is either loosely placed in the main envelop as indicated, or placed in a side chamber. The character of this material, depends upon the temperature and voltages at which the device is operated, as will be hereinafter explained, its purpose being to maintain in the space, vapor at a definite low pressure.

For the evacuation of the device the glass walls of the tube are heated so as to free them from moisture and both the anode and the cathode are heated by passage of current so as to drive out the gases. When an amalgam is to be used as the source of vapor, the metal to be amalgamated, for example, silver, preferably is placed in the envelop before evacuation. The mercury is preferably placed in a side chamber which is kept cool during the preliminary bake-out. The evacuation of the tube is carried out by the most approved methods of incandescent lamp exhaust, and the last traces of gas are removed by either a Gaede molecular pump or by some chemical evacuating means, such as the use of vaporized calcium or magnesium. The last traces of ionizable gases are removed from the electrodes by heating them to incandescence and preferably at the same time operating the grid as the anode for an electron discharge, the impressed voltage being increased step by step as the gas is removed. After the parts of the device and the silver, or other metal to be amalgamated has been freed from gas, mercury vapor is permitted to diffuse into the envelop. For example, clean mercury may be kept at a relatively low temperature in a side chamber during the exhaust. When the exhaust is completed the mercury may be permitted to reach room temperature or even a higher temperature, thus diffusing into the main envelop to form silver amalgam. At room temperature one or two days are required for the amalgamation. All excess unalloyed mercury must be removed from the tube. This may conveniently be done by warming the bulb slightly and surrounding the mercury side tube in a freezing mixture, or in liquid air. The mercury side container may then be sealed off. When evacuation of the envelop has been carried to a pressure low enough to enable the pure electron discharge to take place and ionizable gas has been removed from the anode to a sufficient extent to prevent the blue-glow phenomenon which is an indication of positive gas ionization, the envelop is sealed off. A device thus prepared will operate at ordinary room temperatures with a substantially pure electron discharge between anode and cathode without positive ionization, even when the impressed voltage is as high as 300 to 400 volts, or even higher. However, when the voltage between anode and cathode is within a certain range an irregularity is observed in the electron discharge current, as already described. This voltage range is illustrated by curve 18 in Fig. 2, which will be more fully understood by first considering the connections shown in Fig. 3. In this figure a device 19 constructed as above described is connected in a secondary circuit of a transformer 20, the primary of which is included in series with a condenser 21 in a grounded antenna circuit 22. The grid 9 is connected by a conductor 23 to one terminal of the transformer and the negative terminal of the cathode 2 is connected through a potentiometer 24 and a conductor 25 to the other terminal of the transformer secondary. Connected in shunt to the secondary of the transformer is a variable condenser 26 so that by varying either the capacity or inductance of the circuit it may be tuned to resonance with the incoming oscillations to be detected. The battery 27 serves to heat the cathode to incandescence and also determine the potential of the grid 9 with respect to the cathode. In the plate circuit 28 between the cathode 2 and anode 3, is included a source of direct current, for example, a direct current generator 29 and also a suitable indicator, such as a telephone receiver 30.

In order to receive signals the potentiometer 24 is adjusted so as to maintain the grid at a certain definite potential with respect to one end of the cathode. With a suitable potential between the cathode and anode, for example, 50 to 250 volts, a steady direct current will flow in the plate circuit which will not affect the telephone receiver. When oscillations are received by the antenna and superimposed upon the potential of the grid the electric field about the cathode is changed correspondingly and a decrease of current is noted with each oscillation or series of oscillations, thereby producing sounds in the receiver. With a given electron detector it will be observed that the sensitiveness varies very markedly with the grid potential, there being a certain point at which the signals may be most strongly heard and a variation of grid potential above or below this value produces a decrease of audibility of the signals.

In Fig. 2 there are shown for the purpose of illustration curves of the characteristics of one particular detector made in accordance with my invention. For the curve 18 the ordinates represent grid potentials with respect to negative end of filament and the abscissæ the relayed current in micro-amperes. The curve indicates the current values obtained with a given terminal voltage between the cathode and the anode for the indicated range of grid voltages with respect to the cathode. This current is commonly known as the "plate current." The sensitiveness of the device is indicated by curve 31 which is plotted with the ordinates in grid potential and the abscissæ in percentages of maximum sensitiveness. In other words this curve indicates the degree of change in plate current produced by impressed oscillations at different grid potentials. It will be observed at 1.2 volts the curve of sensitiveness reaches a maximum. It will also be observed that for a certain range of grid voltage on each side of this critical value the plate current exhibits an irregularity and then at higher grid voltages again increases at the rate it had increased before the period of irregularity or off-set in the curve.

In the device here illustrated a sudden change of grid potential as produced by impressed oscillations produces a marked decrease of current in the plate circuit 28 providing the grid potential is not far from 1.2 volts positive. With a pure electron discharge device such as described in Langmuir application, Serial No. 795,610 an increase of positive grid potential will produce an increase of plate current. In the Langmuir device a positive impulse or charge on the grid produces a corresponding increase in the proportion of electron current taken by the grid itself.

On either side of the region of greatest sensitiveness indicated by the off-set of the curve 18 of grid potential the characteristic of my device is substantially that of a pure electron discharge. The vapor pressure necessary to produce this peculiar effect varies with the character of the material used. For mercury vapor in the type of apparatus illustrated the pressure should be between the limits of .00006 and .00040 millimeters of mercury. Sulfur, for example, operates best at a pressure of .0002 to .008 millimeters of mercury. If a greater responsiveness to the received oscillations is desired than can be obtained with the connections illustrated by Fig. 3, my new detecting device may be used in cascade with the pure electron discharge apparatus or relay described in the Langmuir application above referred to. Electrical connections suitable for this purpose are shown in Figs. 4 and 5.

In Fig. 4 the electron relay 32 has its grid circuit included in a local tuned circuit 33, the various parts of which correspond to those described in connection with Fig. 3. It need only be noted that the potential of the grid is determined by a battery 34. The plate circuit 35 contains a generator 36 or other suitable source of direct current of desired voltage. The variable plate current is impressed upon the primary of an air core transformer 37, the secondary of which is connected to the grid circuit 38 of a detector 39 made in accordance with my invention. The incoming oscillations are magnified by the relay 32 which produces in its plate circuit an amplified current similar in character to its received oscillations which is then transformed and detected as already described in connection with Fig. 3. In some cases the relay 32 and my novel detector 39 may be to advantage coupled through a resistance 40 instead of a transformer, as shown in Fig. 5.

In the operation of my novel detector it is not necessary that the source of current in the electrode circuit should be of invariable voltage. An ordinary generator even though its voltage varies slightly due to commutation, and so forth, may be used as indicated in Fig. 3. When using an audion a current source with a steady voltage is necessary as an ordinary generator will cause noises in the telephone. The device is also less affected by "static," or atmospheric disturbances than devices depending on gaseous ionization. It can be operated under the most sensitive conditions without the danger of static causing the discharge to burst into blue glow.

The high apparent resistance of the device renders changes of resistance in the external circuit of little effect. For example, two or three telephone receivers or more may be used in series in the receiver circuit without any noticeable change in the loudness or clearness of the signals.

What I claim as new and desire to secure by Letters Patent of the United States, is:—

1. An electrical discharge device comprising a gas-tight envelop and an electron-emitting cathode and an anode, the space within said envelop being evacuated to such degree that current conduction can take place from cathode to anode by means of substantially pure electron discharge, and means in said envelop for maintaining therein a gas at a definite pressure at which the device possesses a critical region of sensitiveness to changes of electrical field near the

cathode while carrying current independently of gas conduction.

2. A device for detecting high frequency oscillations comprising a cathode adapted to be heated, an anode, a grid located near said cathode, an inclosing envelop, and means for maintaining within said envelop gas at a substantially constant pressure at which the device possesses a region of maximum sensitiveness to oscillations impressed on said grid when said grid is at a critical potential with respect to the cathode, the gas pressure being so low that a discharge between cathode and anode is substantially independent of positive ionization at grid charges materially more positive than said critical potential.

3. A detector for high frequency signals comprising a highly evacuated envelop, a cathode adapted to be heated to incandescence, an anode, a discharge-controlling conductor, and means for maintaining in said envelop gas of such character and pressure that there is a decrease conductivity for variations of potentials of the discharge controlling conductor from a critical potential, the electrodes of said device being freed from gas so completely and the gas pressure therein being so low that the electrical characteristics at current values both lower and higher than the critical region substantially follow the law of pure electron conduction.

4. An electrical discharge device comprising an envelop, an electron-emitting cathode, an anode, a discharge-controlling conductor located near said cathode, said device being deprived of gas to such degree as to be capable of operation with a substantially pure electron discharge at several hundred volts and a vaporizable substance in said envelop.

5. A device for detecting high frequency oscillations comprising an envelop, a cathode adapted to be heated to incandescence, an anode, means for varying the electrical field near the cathode, said device being deprived of ionizable gas to such degree as to operate with a pure electron discharge free from positive ionization at impressed terminal potentials as high as 200 volts and an alloy of mercury and silver in said envelop.

6. An electrical discharge device comprising an envelop, an electron-emitting cathode, an anode, the interior of said envelop being deprived of gas to such low pressure that positive ionization is substantially absent when normally operating and a substance in said envelop exposed to the evacuated space having a vapor pressure of about six to forty hundred-thousandths of a millimeter of mercury.

7. An electrical discharge device comprising an envelop, an electron-emitting cathode, an anode, the interior of said tube being deprived of gas to such low pressure that positive ionization is substantially absent at impressed terminal potentials of several hundred volts, and an amalgam in said envelop exposed to the evacuated space, said amalgam having a vapor pressure at ordinary temperatures of about .00005 to .0004 millimeters of mercury.

8. The method which consists in producing an electron discharge in a space evacuated to such degree that positive ionization of gas present in said space is absent, supplying to said space gas at a constant pressure too low to cause appreciable ionization but high enough to cause a sudden decrease of electron current when the electrical field near the cathode is increased or decreased by high frequency waves.

In witness whereof, I have hereunto set my hand this 19th day of March, 1914.

UNITED STATES PATENT OFFICE.

HAROLD DE FOREST ARNOLD, OF BELLEVILLE, NEW JERSEY, ASSIGNOR TO WESTERN ELECTRIC COMPANY, OF NEW YORK, N. Y., A CORPORATION OF ILLINOIS.

METHOD OF REPRODUCING ELECTRICAL VARIATIONS.

1,118,172. Specification of Letters Patent. **Patented Nov. 24, 1914.**

Application filed July 15, 1912. Serial No. 709,644.

To all whom it may concern:

Be it known that I, Harold De Forest Arnold, a citizen of the United States, residing at Belleville, in the county of Essex and State of New Jersey, have invented a certain new and useful Improvement in Methods of Reproducing Electrical Variations, of which the following is a full, clear, concise, and exact description.

This invention relates to the art of reproducing electric variations; its objects are to secure amplified reproduction of variations of current energy, reproduction without distortion, sensitiveness to minute currents, efficiency, reliability, and noiseless operation.

Among other uses the invention is applicable to telephony, for the purpose of obtaining in an outgoing circuit an amplification of voice currents originating in an incoming circuit.

It is also applicable to telegraphy, and signaling systems generally where amplification is desirable in receiving, recording or reproducing impulses of electrical energy.

In carrying out the invention use is made of the principle of deflection by an electromagnet or other suitable means of an ionized stream which may be produced in any of a number of ways. The mercury arc has been found to be a suitable agent for the purpose. The current variations to be reproduced or reinforced may be impressed on the coils of an electromagnet so situated that the variations of magnetism induced therein produce corresponding deflections of the ionized stream. The invention does not depend upon any effect in current flow which such deflection may have on the circuit of the ionized stream but involves a novel method, which will now be explained, of detecting and utilizing the variations produced by the deflecting agent.

The detecting means of this invention involves the use of an auxiliary circuit which is non-arcing in character and independent of the circuit for establishing the ionized stream, except that it traverses a portion of the vapor of the stream. This auxiliary circuit is maintained by means of an auxiliary cathode or pair of such cathodes immersed in the stream and connected to a source of electro-motive force which may be separate and distinct from the source producing the stream itself, the circuit being completed through an anode which may likewise be immersed in the stream. There is thus established in the vicinity of the auxiliary cathode or cathodes an electrical field, which causes in the auxiliary circuit a flow of current the intensity of which is directed dependent upon the distribution of ionization in the auxiliary cathode field.

The invention will be more fully understood by reference to the accompanying drawings wherein—Figure 1 shows a system of circuits and apparatus by which the method hereinafter claimed may be carried out and Fig. 2 shows in elevation and cross section the apparatus of Fig. 1 separated from the circuits.

Referring to the drawings, the means for producing the ionized stream, which in this instance I have shown as a mercury arc apparatus, comprises a main chamber 1, with a horizontal branch 2 and a condensing chamber 3 together with a mercury cathode 4, an anode 5 of carbon or other suitable material, and a starting mercury anode 6. Supported within the main chamber 1 are a pair of auxiliary cathodes 7, 8 which are shown semi-cylindrical in form and slidably separated from each other and from the walls of the chamber. Extending downwardly between the auxiliary cathodes is an auxiliary anode 9. The auxiliary cathodes and the auxiliary anode may be of platinum, or other suitable conducting material. Leading in conductors preferably of platinum wire are provided for the several electrodes of the device.

As the means for deflecting the ionized stream, I have shown an electromagnet 10, the means of support of which is not shown. Such magnet comprises a pair of coils 11, 12, surrounding inwardly extending pole pieces the outer ends of which are joined by a semi-circular yoke 13. The pole pieces present their faces to opposite sides of the main chamber 1 in the region of auxiliary cathodes 7, 8 so that the lines of force between the pole pieces are in a direction transverse to the direction of flow of the ionized stream in the chamber 1 and operate to deflect the stream in the direction of one auxiliary cathode or the other, according to the direction of the current in the magnet coils.

The system shown in Fig. 1 comprises five circuits—(1) an incoming circuit 14 including the coils 11, 12 of the electromagnet 10 and the secondary of an induction coil 15, the primary of which is in (2) a local circuit containing a source of current and a transmitting device such as the telephone transmitter 16; (3) an outgoing circuit 17 including a receiving device such as the telephone receiver 18 and the secondary winding 19 of a transformer 21; (4) an energizing circuit for the mercury arc comprising a battery 22, impedance coil 23 and resistance coil 24, this circuit being connected, one terminal to the anode 5 and the other terminal to the cathode 4, and having a starting branch 25 connected, one terminal to the battery 22 and the other to the starting anode 6 and including a starting key 26; and finally (5) the auxiliary detecting circuit including a battery 27, one terminal of which is connected to the auxiliary anode 9 and the other branching through balanced primary windings 28 and 29 of the transformer 21 to the auxiliary cathodes 7 and 8 respectively.

The impedance coil 23 and resistance coil 24 provide a balance for the mercury arc circuits to maintain a steady flow of current therein which, when once established as by tipping the tube, closing the circuit at the starting key 26 over the path 22, 23, 24, 4, 2, 6, 25, 26, 25, 22 and then releasing the key 26 is maintained automatically over the path 22, 23, 24, 4, [illegible], 1, 5, 22 which includes the ionized arc stream in the main chamber 1. This stream passes by and in contact with the auxiliary cathodes 7 and 8, filling the region between them, and rendering the auxiliary circuit conductive so that current flows from the battery 27 dividing through the primary windings 28 and 29 of the transformer 21 to the auxiliary cathodes 7 and 8, to and through the ionized vapor therebetween and by way of the auxiliary anode 9 back to the battery 27. It is noteworthy of this auxiliary circuit that it is non-arcing in character and that the potential difference existing between the auxiliary electrodes is independent of, and in fact may be very much greater than, that existing between the electrodes of the arc stream. At the same time the current flow in the auxiliary circuit may be very much less than that in the arc circuit. For example, in one particular embodiment of the apparatus the potential difference existing between the auxiliary anode 9 and the auxiliary cathodes 7 and 8 was 1[illegible]0 volts whereas that between the anode 5 and cathode 4 of the arc was 30 volts. The current flow in this instance was .04 ampere in the auxiliary circuit and one ampere in the arc circuit. The primary coils 28, 29 of the transformer 21 are wound differentially in the auxiliary circuit, that is to say, in such a direction with respect to each other that the core thereof under normal conditions of the circuit is not magnetized. The normal current flows equally or approximately so in the two branches, this being due to the symmetrical arrangement of the auxiliary cathodes 7, 8 with respect to the ionized vapor in the space between them. When, however, the electromagnet 10 is energized by current received over the incoming circuit, 14, a magnetic field is produced which deflects the stream toward one electrode or the other. The effect of this is a change in the distribution of ionization in the field or region adjacent the auxiliary cathodes and current will flow with increased strength through one primary winding of the transformer and with decreased strength through the other thereby inducing current in the secondary winding which is transmitted over the outgoing circuit 17 and recorded or made manifest in the receiving instrument 18. In this manner minute variations of current energy such as those transmitted over great distances by a telephone or signaling device and delivered to the instrument by the incoming circuit 14 are reproduced and amplified in the outgoing circuit 17. The extremely small mass of the ionized vapor which is deflected by the electromagnet enables the reproduction of current variations to be accomplished without distortion. By reason of the non-arcing character of the detecting circuit the relaying of current variations is accomplished without disturbing or "noisy" currents in the outgoing circuit, this being of especial importance in telephone transmission systems.

I have illustrated and described two auxiliary cathodes and a branched circuit through balanced primary windings 28 and 29, for the reason that I have found that such arrangement produces the best results. My fundamental invention would, however, be embodied in an arrangement in which only one auxiliary cathode and one primary winding are employed. Also the auxiliary anode 9 may be omitted and the battery 27 may be connected with the anode 5, without departing from the spirit of my invention. Moreover, while I prefer to use two magnet coils 11 and 12, one of them may be omitted, and indeed, the arc stream may be caused to be deflected by electro-static instead of electromagnetic means.

I claim:

1. The method of reproducing electrical variations which consists in establishing an ionized stream, maintaining a circuit including a transverse path within said stream, applying at a point within said path a variable deflecting force to said stream, and producing thereby current variations in the said circuit.

2. The method of reproducing electrical variations which consists in establishing an arc, maintaining an auxiliary non-arcing circuit in a transverse path within said arc, applying at a point within said path a variable deflecting force to said arc, and producing thereby current variations in said auxiliary circuit.

3. The method of reproducing electrical variations which consists in establishing an ionized arc stream, maintaining an auxiliary non-arcing circuit including a transverse path within said stream, applying at a point within said path a variable deflecting force to said stream and producing thereby current variations in the said auxiliary circuit.

4. The method of reproducing electrical variations which consists in establishing an ionized stream, maintaining a balanced non-arcing circuit having two paths through a portion of the ionized vapor of said stream, deflecting said stream to and fro between said paths in accordance with current variations in an incoming circuit and transforming in an outgoing circuit the current variations thereby produced in the balanced circuit.

In witness whereof, I hereunto subscribe my name this 13th day of July A. D., 1912.

UNITED STATES PATENT OFFICE.

PETER COOPER HEWITT, OF RINGWOOD MANOR, NEW JERSEY, ASSIGNOR TO COOPER HEWITT ELECTRIC COMPANY, OF NEW YORK, N. Y., A CORPORATION OF NEW YORK.

VAPOR ELECTRIC APPARATUS.

1,025,464. Specification of Letters Patent. Patented May 7, 1912.

Continuation of application Serial No. 206,179, filed April 21, 1904. This application filed March 23, 1908. Serial No. 422,618.

To all whom it may concern:

Be it known that I, PETER COOPER HEWITT, a citizen of the United States, and resident of Ringwood Manor, county of Passaic, State of New Jersey, have invented certain new and useful Improvements in Vapor Electric Apparatus, of which the following is a specification.

My invention relates to that class of electrical apparatus in which electric currents are caused to traverse an inclosed gas or vapor. The device embodying these features may be used for yielding light or, under certain conditions, producing a flow of current in a continuous direction from an alternating source of supply, and various other purposes. Devices of the same general character are described in certain patents issued to me on September 17, 1901, and reference may be had thereto for details as to the general plan of exhausting the inclosing chamber and securing the proper conditions of the inclosed gas or vapor. It is now well-known that devices of this character oppose a resistance to the initial passage of current therethrough, but that when this resistance has once been overcome, as by the application of a current of high potential for instance, current will continue to flow under the influence of moderate difference of potential.

The present invention relates more particularly to means for initiating the flow of current through apparatus of this class. I have found that if an actual conducting path through the gas or vapor is provided in the first instance from a negative electrode to a positive electrode of the device, and if current is caused to flow through this conducting path and the path is then interrupted at or near the negative electrode, the current will flow through the gas or vapor between the electrodes in preference to jumping or bridging the comparatively small gap between the separated terminals of the interrupted conducting path. In practice, I have adopted a form of apparatus in which the negative electrode is provided with a conducting prolongation or extension which makes contact either with the other electrode or with an extension therefrom, and I have provided automatic means for the opening of the conducting path thus formed inside the containing vessel, with the result already described. In the original experiments with this class of devices, difficulty was encountered in obtaining a solid conductor which could be freed from gases and foreign materials within a practical time while on the pump. Such lamps after having apparently been suitably exhausted would become inoperative within a comparatively short time which was attributed to the giving off of deleterious gases from the extension of the negative electrode, thus rendering the lamps difficult to make practically and impairing their durability when made. I have devised various ways of overcoming this difficulty among which may be mentioned, constructing the extension from the negative electrode of very thin material and heating it by reason of the ohmic resistance offered to the passage of current through it while on the pump. It was also overcome by allowing the negative flame to lick it from the top to the bottom, thus heating it locally all over in spots while still on the pump. The material forming this extension may also be treated externally from the lamp, before putting on the pump, thus obviating the major part of the difficulty of removing the gases while the final pumping is in progress. The material may be of soft iron, carbon, graphite, or other suitable material.

The details of a convenient embodiment of my invention are described herein and illustrated in the accompanying drawings in which Figure 1 illustrates one form of apparatus adapted to carry out the invention; and Figs. 2, 3, 4 and 5 illustrate details and modifications.

In the first figure of the drawings, 1 represents a suitable inclosing chamber which, when the device is to be used as a lamp, will generally be made of glass or other suitable transparent material. The chamber contains a suitable gas or vapor, such for example, as mercury vapor. In the present instance, I have shown a negative electrode, 2, as consisting of a small quantity of mercury, and have shown this electrode as being connected with an external conductor 9, by a leading-in wire, 3. The latter is flexibly connected with the base of the extension 8, which is surrounded by the mercury and in electrical connection therewith. The rod, 8, which is thus in contact with the mercury extends longitudinally through the container 1, forming, so to speak, a prolongation or extension of the negative electrode. The extension 8 may conveniently consist of a relatively stiff piece of conducting material such, for instance, as iron, carbon, chromium, or other suitable conductor. Should some nonmagnetic material be selected for the extension 8, its remote end may be provided with a magnetizable material to constitute an armature, as will be explained later on. Near its remote end the extension 8 is here surrounded by a loop or ring, 5, constituting the main portion of the positive electrode of the apparatus. The said loop or ring is connected by an extension, 6, with a leading-in wire, 7, constituting the means of connection with the external circuit.

When the apparatus is mounted, say in a vertical position, the extension 8 rests against the inner edge of the ring electrode 5, thereby completing a conducting path through the container 1 by way of the leading-in wire 7, the extension 6, the ring electrode 5, the extension 8, the negative electrode 2, and the leading-in wire 3. The connection of the positive electrode 5 to the external circuit conductor, 10, is made through a coil, 11, having a magnetizable core, 12. To start the device into operation, the circuit 9—10 is closed and current passes through the device by way of the conducting path already described. In this way the electro-magnet 11—12 is vitalized and acts magnetically upon the adjacent end of the extension 8 whereby the said extension will be lifted out of contact with the ring 5. Thereupon the current will pass from the ring through the intervening vapor path to the extension 8, after which the current very quickly chooses the path of gas or vapor in the container, and instead of continuing to traverse a portion of the extension 8, passes directly through the gas or vapor path to the surface of the electrode 2. The position of the magnet 11—12 may be such as to draw the extension 8, over against an insulating block or coating, 13, carried by the ring 5; or it may cause the extension to stand free within the ring and out of contact with any portion thereof.

The extension 6, may terminate in circular form, as shown in cross-section in Fig. 3, or in an electrode of Y-shape, as shown in Fig. 4, or in an electrode having other suitable configuration.

In Fig. 2 I have shown a modification illustrating the invention as applied to a multiphase electric circuit. The source, 30, is here shown as a three-phase generator, which may be either a transformer or any other suitable source of three-phase currents. It is not necessary that the multiphase circuit should be a three-phase circuit, it being readily possible to adapt the invention to circuits carrying any desired number of phases. The neutral point, 31, of the generator is joined by a wire, 9^a, with the leading-in wire 3. The terminals of the generator are connected by wires, 10^a, 10^b, and 10^c, respectively, with positive electrodes 15^a, 15^b, and 15^c, within the container 1. The magnet 11—12 is here included in the conductor 9^a, and a switch, 20, is provided for controlling the circuit. A work circuit is shown at 21. The electrode 5 is ring shaped as before and surrounds the open end of the extension 8. The latter simply rests within the mercury electrode, 2, without being mechanically linked to the leading-in wire. For energizing the magnet 11—12 and initiating the flow of current, I may use a suitable source, 14, of continuous electric currents and I may provide its circuit with a switch, 33, by means of which the said source may be cut into and out of circuit. This circuit may be independent of the work circuit. Assuming that the said switch is closed, the closure of the switch 20 will then complete a circuit from the source 14 through the leading-in wire 7, the extension 6, the electrode 5, the extension 8, the electrode 2, the leading-in wire 3, and the conductor 9^a. This will cause the extension 8 to be lifted out of contact with the ring electrode 5, and it will be held out of contact so long as the circuit to the source 14 remains closed. As to the operation of the device under the influence of multiphase currents, it may be said that successive phases pass through the device to the electrode 2 from the electrodes 15^a, 15^b and 15^c, and inasmuch as current from one of these electrodes begins before that through another ceases, the apparatus will be kept in operative condition.

In Fig. 5, I have shown a modification in the arrangement of the apparatus in which the negative electrode is put at the upper end of the device in the bottom of a bent-over extension and hangs downward through the tube and passing through the ring 5 at the lower end. The magnet 11 may be so placed as to swing the extension into contact with the electrode when it is desired to make contact therewith and it will be released when the circuit of the magnet 11 is broken, or it may be made to operate in the same manner as described with reference to Fig. 1. The magnet 11, in this instance, is shown as being connected in a separate circuit provided with a switch of any suitable character for temporarily closing its connection.

The present application is a continuation of applicant's case Serial Number 204,179, filed April 21st, 1904.

I claim as my invention:—

1. In a system of electrical distribution, the combination with an alternating cur-

rent source, a rectifier therefor comprising a completely exhausted container and electrodes therein including a plurality of anodes and a vaporizable reconstructing cathode and connections between said anodes and terminals of the source and a connection between the cathode and an intermediate point of said source, of a separate direct current source connected between the intermediate point of the alternating source and a separate anode within the container, means for connecting and disconnecting said additional anode to and from said cathode within the container and automatic means responsive to the rectified current from said alternating source for operating said means, together with non-automatic means for controlling the direct current source.

2. In a system of electrical distribution, the combination with an alternating current source, a rectifier therefor comprising a completely exhausted container and electrodes therein, including a plurality of anodes and a vaporizable reconstructing cathode and connections between said anodes and the terminals of the source and a connection between the cathode and an intermediate point of said source, of a separate direct current source connected between the intermediate point of the alternating source and a separate anode within the container, means for connecting and disconnecting said additional anode to and from said cathode within the container, a magnet coil located in the said first named connection to the intermediate point of the alternating source for operating said means, together with non-automatic means for controlling the direct current source.

PETER COOPER HEWITT, OF NEW YORK, N. Y., ASSIGNOR TO PETER COOPER HEWITT, TRUSTEE, OF SAME PLACE.

METHOD OF MANUFACTURING VAPOR OR GAS LAMPS.

SPECIFICATION forming part of Letters Patent No. 682,699, dated September 17, 1901.

Application filed April 5, 1900. Renewed May 2, 1901. Serial No. 58,510. (No model.)

To all whom it may concern:

Be it known that I, PETER COOPER HEWITT, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented certain new and useful Improvements in Methods of Manufacturing Vapor or Gas Lamps, of which the following is a specification.

My invention relates to the class of electric-lighting apparatus in which an electric light is produced by the action of electric currents upon a vapor or gas.

The object of the invention is to provide an electric lamp having a gas of the proper density and characteristics for producing light conveniently and efficiently by the action of electric currents.

Prior to my invention it had been proposed to produce within a so-called "vacuum-tube" electric light by means of electric charges, and in some instances it has been proposed to pass electric currents through tubes containing a vapor or gas. None of these devices, so far as I am aware, were capable of being operated in a commercial manner. Among other defects may be mentioned the fact that they would not receive current in such manner as to be self-regulating in any commercial degree. Moreover, their resistances were not controllable in such manner as required for commercial use.

My invention aims to produce a lamp which may be used upon commercial circuits with convenience and which shall be highly efficient and durable.

In the manufacture of my lamp it is essential that the containing-chamber shall be freed from deleterious gases and substances and caused when finished to have a suitable quantity of gas or gases at the proper densities. These results I accomplish by manufacturing the lamp in a manner which will be more particularly described in connection with the accompanying drawing, which illustrates diagrammatically the lamp and the circuits and apparatus for manufacturing it.

Referring to the drawing, 1 represents the lamp-chamber, consisting in this instance of a tube which may, if desired, contain a slight enlargement 4 at one end. It is provided with two electrodes 2 and 5, suitably located within the chamber, and leading-in wires 7 and 8 connect with these electrodes, respectively

The lamp is during the process of manufacturing connected with a suitable exhaust-pump 10 by means of a pipe 11. The lamp structure is exhausted by means of the pump 10, and I usually heat it during the process of exhaustion—as, for instance, by the flame of a Bunsen burner 12 or in any other convenient manner. Previous to placing the lamp upon the pump it may be thoroughly washed with alkalies and acids to remove the impurities. When the atmosphere has been pumped out from the structure, a quantity of gas of the same kind as that which it is desired to use in the completed lamp may be let into the lamp either through exhaust-tube 11, or, if more convenient, through a tube 14, which is here shown as connected with the lower end of the lamp and as leading from a suitable reservoir 15, containing the gas. The exhaust-pump 10 is operated to pump out the gas thus admitted, and the washing by means of this gas is continued as long as may be necessary.

In order to heat the electrodes within the lamp as well as the whole lamp structure, it may be connected with a suitable source of electric currents 16 17, and for the purpose of applying a higher difference of potential to the lamp than that with which it is intended to ultimately operate it a transformer 18 may be employed, having its primary coil 19 suitably connected with the source 16 and 17, and, if desired, through an interrupter 20 of any convenient character, while the secondary coil 21 is connected in the circuit leading to the lamp. The higher difference of potential thus impressed upon the terminals of the lamp acts upon the vapor within the lamp, at first causing it to be slightly luminous. By means of a reversing-switch 22 the connections of the circuits may be reversed, so as to render the electrodes 2 and 5 alternately cathodes and anodes. I have found that the cathode will become highly heated by the action of these currents, and thus throw off occluded gases and be subjected to such chemical reactions and changes as might otherwise occur in the lamp after it is completed. By thus treating the lamp the impurities and such materials as would exercise a deleterious effect upon the lamp may be removed. When the lamp has thus been sufficiently treated, an excess of the gas with which it is to be operated is admitted to the chamber or created in it, and while the terminals of the lamp are subjected to the currents of higher electromotive force and also of the electromotive force with which it is designed to be operated, the excess of gas is pumped out until a point is reached where the gas becomes sufficiently conductive to receive considerable currents and to become highly luminous. When the proper conditions are reached, the action of the lamp is very noticeable and the amount of light yielded is vastly greater than that produced by the action of the higher-potential current. In some cases it may be desired to operate the lamp with currents of considerable quantity repeatedly before finally sealing off the lamp. By noting the operation of the lamp and the quantity of current received it may be readily determined when the lamp is charged with a gas of the proper density, and the lamp is then sealed off and completed. The densities required on the part of the gases differ with different gases used, and the electromotive force and quantity of current received by the lamp are dependent in a measure upon the length and cross-section of the gas path within the lamp, as well as upon the kind of gas employed, and also upon the kind of electrodes. By following the instructions herein given, however, the rules for governing each different gas, as well as the dimensions of the lamp structure, may be readily determined, and the proper point of time at which to seal off the lamp is indicated in the manner referred to. I have obtained excellent results from such gases as nitrogen.

The tendency of the electric current during the operation of the lamp is to pass to the farthest portions of the electrodes, and I therefore usually construct the lamps so that the portions of the electrodes 2 and 5 which are nearest to each other are the only exposed portions thereof, protecting the more remote portions by the covering of insulated material—such, for instance, as sleeves 23, of porcelain or other substance—which will not be acted upon by electric current, fitting tightly over the leading-in wires. The shapes of the electrodes may be variously modified. I have found, for instance, that a somewhat conical face serves well for the anode and a concave face for the cathode; but these shapes may be variously modified. The electrodes are made of suitable material—such, for instance, as iron, platinum, &c.

It will of course be understood that instead of admitting an excess of gas and then withdrawing it for the purpose of producing the required density a higher degree of exhaustion may be obtained and then the gas admitted gradually until the proper condition is reached.

In certain other applications filed by me April 5, 1900, Serial Nos. 11,605, 11,606, and 11,607, I have described a lamp of the general character of that described and claimed herein and its method of operation and process of manufacture.

The invention claimed is—

1. The hereinbefore-described process of manufacturing lamps having a gas path, which consists in heating the containing-chamber, exhausting the gaseous contents therefrom, washing the chamber with a gas of the same character as that with which it is to be provided, subjecting the interior of the chamber and the electrodes to the action of electric currents, creating within the chamber such a density as will permit the gas to receive currents of considerable quantity under the influence of moderate electromotive force, and then sealing off the lamp.

2. In the process of manufacturing lamps having gas or vapor serving as a path for the current between the electrodes, the method of cleansing the lamp which consists in electrically heating the electrodes and washing the lamp by a gas or vapor of the same character as that which is to constitute the gas or vapor path when the lamp is complete.

3. The process of producing within a gas electric lamp the required density of gas which consists in first thoroughly cleansing the lamp from deleterious materials and then providing within the lamp an excess of the gas, gradually reducing the density of the same, and applying an electromotive force of moderate potential and superposing alternating or intermittent currents of higher potential to the terminals of the lamp until such a density is attained that currents having the lower potential will traverse the lamp, and thereafter sealing off the inclosing chamber of the lamp.

4. The method of producing within a gas electric lamp the density of the gas required for operating the lamp under the influence of moderate electromotive force, which consists in thoroughly cleansing the lamp, applying to the terminals of the lamp an electromotive force of higher voltage than that with which the lamp is intended to operate and applying a difference of potential approximately the same as that with which the lamp is designed to operate, gradually changing the density of the gas within the containing-chamber until currents traverse the lamp under the influence of the lower electromotive force, substantially as described.

PETER COOPER HEWITT, OF NEW YORK, N. Y., ASSIGNOR TO PETER COOPER HEWITT, TRUSTEE, OF SAME PLACE.

METHOD OF MANUFACTURING ELECTRIC LAMPS.

SPECIFICATION forming part of Letters Patent No. 682,692, dated September 17, 1901.

Application filed April 5, 1900. Serial No. 11,807. (No model.)

To all whom it may concern:

Be it known that I, PETER COOPER HEWITT, a citizen of the United States, and a resident of New York, in the county of New York and State of New York, have invented certain new and useful Improvements in Methods of Manufacturing Electric Lamps, of which the following is a specification.

My invention relates to methods of manufacturing a novel class of electric-lighting apparatus.

The general purpose of the invention is to produce an electric-lighting device capable of converting electric energy into light through the agency of vapors or gases as efficiently as possible and with simple and durable apparatus.

In the ordinary conversion of electric energy into light a large amount of the energy is wasted in heat, and while the development of heat is usually, if not always, attendant upon the development of commercial light, yet from theoretical considerations it may be assumed that the efficiency of a light-producing device, other things being equal, would be increased in approximate proportion as the development of heat is suppressed.

My invention aims to produce a device capable of yielding light by the conversion of electrical energy, with the coincident production of as moderate amount of heat as practicable. Gases or vapors produce this property in a greater degree than matter in any other state, and therefore they offer a field of operation in which the highest efficiencies can be obtained if proper means are devised for rendering the gases or vapors light-emitting under the influence of electricity.

It has been proposed to obtain light by the passage of alternating or intermitted electric currents of very high frequency through a more or less rarefied gas contained within hermetically-closed tubes, such gas being so acted upon by the currents as to become luminous. This class of apparatus, commonly known as "Geissler-tubes," has been found for various causes to have no commercial utility as a means of illumination. It has also been proposed in some instances to pass electric currents through two electrodes consisting of bodies of mercury contained in hermetically-closed tubes and to obtain light from the electric arc between the two mercury electrodes; but prior to my invention no such devices, so far as I am aware, have been produced which are suitable for commercial use. They have usually been started by bringing the two bodies of mercury constituting the electrodes into actual contact with each other and then separating them, the electric current then being caused to arc across from one electrode to the other. Such method of starting has been found impracticable for any extended use and requires the presence of a considerable outside resistance to prevent an excessive current-flow when the bodies of mercury are in contact, and even when started they have been incapable of commercial operation with efficiency or for any considerable period of time. These and other difficulties have rendered such devices impracticable for use upon circuits in which the electromotive force is liable to vary, as in the ordinary commercial systems of electric lighting or even in connection with other circuits, such as those supplied by storage batteries, and they have little or no value, except, perhaps, for special scientific or laboratory experiments. These devices, so far as I am aware, have not been capable of operation for any considerable period, if at all, by the conduction of current from one electrode to the other, but have been essentially arc-lamps.

The exact distinctions between an arc and conduction not involving an arc are somewhat difficult to define, although not difficult to detect in practical operation. It is noticeable, however, that in the case of an arc there is intense heating of both the positive and negative electrodes, but particularly of the positive electrode, and the current passes from the electrodes into the conducting-vapor at definite points or positions, whereas in the other form of conduction the effect is to produce a halo around the electrode, except that a dark space appears at or around the electrode. This space and its appearance seem to differ with different vapors used; but there is always a marked and well-defined difference between it and an arc, and when in the process of manufacture the last trace of arc disappears it is plainly noticeable. In the other form of conduction little or no heat is developed at the points where the current passes from the electrode into the vapor. Moreover, in the case of the arc there appears to be a narrowing at or near an electrode, whereas in the other form of conduction the body of light is of practically the same dimensions throughout the space between the electrodes or between points in close proximity to the electrodes. An arc, moreover, is striated, a condition which does not appear to be present in the other form of conduction. Again, the temperature established by the arc in any one place with a given flow of electric energy appears to be far in excess of that produced by a flow of the same amount of energy in the other form of conduction.

The lamps which I have produced do not operate upon the arc principle, but possess the characteristics of this special form of conduction. It is, moreover, essential that the proper adjustment of the resistance of the vapor path should be obtained, and I have found that this result can be secured in the case of vapors conducting in this manner, so that the electromotive force with which the lamp is adapted to be operated can be predetermined with as great a degree of accuracy as is usual in the manufacture of the ordinary incandescent lamps having carbon filaments, and the manner in which the resistance shall vary can be controlled in vapor-lamps with a much wider range of controllable resistance than is the case with a carbon filament, as the resistance of the carbon is a fixed factor, while the vapor resistance may be selected to vary at will within wide limits.

It does not appear to have been appreciated prior to my invention that such a control of resistance on the part of a vapor was possible or practicable, and, as a matter of fact, in the forms of lamp hereinbefore referred to, where an arc is established between bodies of mercury, such control has not been obtained.

Under proper conditions certain vapors and also certain materials which normally exist in the form of gases may be caused to remain in such condition as to convey electric currents under the influence of moderate electromotive forces after a current-flow has once been established. By properly correlating the resistances between the respective electrodes and the vapor or gas and the resistance of the vapor or gas path itself and providing a proper heat-radiating capacity a lamp may be produced which will take considerable currents at moderate electromotive forces and be self-regulating to such a degree as to permit of its use upon commercial circuits even though their electromotive forces may fluctuate through wide limits.

To render the lamp as stable and self-regulating as possible upon the circuit, it should have the resistance between the respective electrodes and the gas or vapor path reduced as much as possible, so that these resistances relative to the resistance of the gas column shall be small. The gas or vapor path then constitutes the principal portion of the resistance of the lamp, and as the electromotive force at its terminals increases the total opposition to the passage of current may be made to increase also. This may be due in a measure at least to the fact that the greater amount of current flowing under the increasing pressure tends to develop a higher current, which in turn tends to increase the resistance of the lamp, so that a balance can be effected, rendering the lamp self-regulating. I do not, however, desire to be understood as advancing this theory of its regulation as the only one or as being necessary, but merely one which may be advanced from the results obtained.

Some materials when in a gaseous or vaporized state possess the capacity of emitting light under the influence of electric currents in a much higher degree than others. The vapor of mercury is efficient as a light-yielding material, and owing to its molecular weight and its low boiling or vaporizing point it is well suited to the purposes of my invention. Moreover, it readily serves under the influence of the current to transfer the heat generated in the lamp to convenient points for radiation. Some of the materials normally existing in the form of gases may, however, be used—such, for instance, as nitrogen. The amount of light, however, which may be obtained from nitrogen per unit of length appears to be less than that which can be obtained from mercury vapors, other things being equal. The spectrum is also a matter to be considered in determining the material to be used. Mercury gives a light which is clear and white, but wanting in red rays, so that while useful for many purposes it may be undesirable for others. Lithium and similar materials yield spectra with red and other colors. Nitrogen and other gases develop red rays in abundance, and when combined with the mercury rays a beautiful result is obtained. The selection of the material for the vapor or gas must be determined by the conditions and requirements. The invention will be more particularly described with reference to mercury vapor as a matter of convenience and clearness, being among the most convenient to practice the art.

The lamp should be constructed to utilize as far as possible all the resistance of the lamp in the conversion of the electrical energy into light; but as there may be more or less heat developed the structure should be such as will radiate the heat at a suitable rate. Usually it is advantageous to employ a cooling-chamber at some portion of the device outside the path of the current. In the case of mercury, for instance, an enlargement of the tube may project a distance beyond one of the electrodes, so that the excess of heat will be radiated. In some instances it is practicable to cause the radiation to take place through the walls of the tube surrounding the gas column at a sufficient rate to meet the requirements. If the temperature of the lamp is allowed to become too high, the lamp is liable to extinguish itself. When a fixed gas is used or vapors under such conditions that their densities cannot be unduly increased by heat in the tube, then the cooling-chamber may be dispensed with. The lamp may be made of such a size as to render a special cooling-chamber unnecessary.

The ability to start the lamp readily is of the utmost importance, gases appearing to present a greater resistance to the passage of the current before the current is passing than after, and I have found that certain materials added to the lamp before or while in the process of manufacture produce a condition which makes it possible to start a current under a moderate increase of electric pressure, and thereupon the continuous or an alternating current of low pressure readily traverses the lamp, producing an intense enduring light. I have obtained excellent results by the use of an independent substance for effecting the starting of the lamp which produces a preliminary condition favoring the passage of current. One of the substances which I have used is sulfur or its compounds—for example, a small quantity of the sulfid of mercury introduced at the same time as the mercury when mercury is employed for forming the vapor. The tube containing these materials is then heated by any suitable means, the air, moisture, and foreign gases being pumped out by a suitable air-pump. I have found it advantageous during the process of exhaustion to heat the tube by convenient means until a vacuum is formed and to then subject the contents of the tube to the action of an electric current of high voltage. I am able to thus produce more or less heat throughout the length of the tube and produce such chemical reactions as may occur under the influence of the current and drive out foreign or deleterious gases and substances, leaving fairly pure mercury and a resultant sulfur compound, the exact nature of which I am not prepared to state with definiteness, although from such tests as I have been able to apply it would seem probable that it is a compound of mercury and sulfur containing a less proportion of sulfur than exists in the form of sulfid of mercury. Its effects seem quite different from that produced by pure red or black sulfids of mercury such as I have been able to make or procure in the markets. With this material present in the tube it is possible at starting cool to transmit an alternating or intermittent current from one end of the tube to the other with a much lower electromotive force than is required if the sulfur compound or its equivalent were not present. It seems also desirable to free the tube as far as possible from certain foreign substances, and particularly from oxygen, and I sometimes treat the tube with a bath of heated hydrogen before placing on the pump and also when the lamp is being exhausted. I have found it sometimes advantageous to use interrupted currents of high voltage flowing in a given direction and to first constitute one of the electrodes the anode and the other the cathode and then to reverse the direction of the currents. I usually employ solid materials—such, for instance, as pure iron or other suitable substance—for one or both of the electrodes, and by thus constituting the respective electrodes alternately anodes and cathodes during the process of exhaustion I am enabled to heat each of them to a very high temperature, and thus drive out any occluded gases and foreign materials and produce any chemical reactions in them that might otherwise occur later on and ruin the efficiency of the tube. While the lamp is thus being treated and exhausted, I connect the electrodes through a variable resistance with a suitable source of current of moderate electromotive force—such, for instance, as one hundred and ten or two hundred and twenty volts—the application of the high potential being also continued. In practice I find that the lamp should be run on the pump with a current at least equal to or, better, in excess of the current it is intended to afterward operate with. As the lamp approaches completion it suddenly becomes intensely luminous by reason of the passage of a considerable current of moderate potential from this source. The high-voltage current may then be temporarily withdrawn and the lamp further treated by current of low potential. Usually, however, it is desirable to use the currents of interrupted high potential at intervals, as they are useful for heating the electrodes and effecting the chemical changes, as above referred to. When the lamp ceases to give off further foreign gases, it may be sealed off, and it is then in condition for operation.

When no starting material is present in the lamp, it is possible to start by heating it by any convenient means—such, for instance, as a Bunsen burner or an electric heating-coil of any convenient construction—and simultaneously applying to the terminals a difference of potential substantially equivalent to that upon which the lamp is designed to operate and at the same time a boosted electromotive force to enable the regular current to pass; but in the case of fixed gases, owing to the electric phenomena the exact nature of which I am not as yet able to state, the lamp lights up and when once lighted will continue in operation as long as required. When, however, the starting material is used, the lamp may be started without preliminary heating by means of electric currents of the proper electromotive force, usually higher than that upon which the lamp is normally intended to run. This may be conveniently done by placing in the circuit leading to the lamp the secondary coil of a transformer the primary of which is connected with the supply-circuit through a suitable circuit-interrupter, or an alternating current from a suitable transformer may be used, the purpose being to first cause a current to pass through the space between the electrodes, which then appears to afford a path for the operating-currents of moderate potential. The readiness with which currents of lower electromotive force are caused to flow when a lamp provided with the starting material has been subjected for an extremely short period to a higher electromotive force would indicate that the starting is not in this case due to the heat development of the current, but to some other electrolytic or electrochemical action, the exact nature of which it is difficult to determine. For the purpose of constructing the lamp it is not essential that the theory of the action should be determined.

I have found that other materials than sulfur and mercury may be used to produce the starting material in the lamp. For instance, I have employed selenium and mercury with good results, and also phosphorus and mercury and other materials. After the lamp is started it is probable that the starting material does not continue to act as a current-carrier, but that it is forced out of the path of the current or undergoes a change, but when the lamp is again cooled it resumes the proper relation and condition to be availed of for again starting. I have found it advantageous when the lamp is to be started without heating and by means of moderately high voltage currents to surround the glass or wall in the neighborhood of one of the electrodes, or in the case of an alternating-current lamp each of the electrodes by a band of conducting or semiconducting material—such, for instance, as foil—which in turn is placed in electrical connection with the other electrode or grounded by means of a small conductor. This device appears to lessen or neutralize, to a certain extent at least, the surface tension or static charge which gathers about the electrode during the application of the starting-current, and it reduces the effective starting resistance of the lamp. A lamp which could be started only by extremely high potential currents, if at all, without this band, may be started without difficulty when it is present. When the lamp is once in operation under the influence of alternating or continuous currents of low pressures, the presence of the conducting-band seems to no longer exercise its function to the same degree, although it may remain without interfering with the operation of the lamp, as it is insulated from the neighboring terminal of the lamp.

In the accompanying drawings, illustrating my invention, Figure 1 represents one form of a complete lamp. Fig. 2 illustrates, partly in diagram, an organization of apparatus for exhausting and treating the lamp during exhaustion.

Referring to the figures, 1 represents a glass tube of such dimensions as may be required—say, for example, a tube of three-quarters of an inch in diameter and two or three feet in length and having a wall of such thickness as not to be fragile. The particular dimensions of the tube to be chosen are determined by the electromotive force and the current with which it is to be operated and other considerations which will be hereinafter pointed out. This tube is provided with two electrodes, (indicated at 2 and 5, respectively.) If the lamp is to be run by continuous current, the electrode 2 is usually the anode and the electrode 5 the cathode. In the drawings I have shown the electrode 2 as being of an inverted-cup shape; but other forms may be employed—such, for instance, as a closed spherical, oval, cylindrical, and other shapes. I have obtained excellent results by using a pure iron for this electrode; but other metals may be substituted. It is suspended within or near the neck of an enlargement or chamber 4, which I usually employ, this chamber serving to increase the heat-radiating capacity of the lamp and to retain impurities. The electrode 2 is suspended by leading-in conductor 7, of platinum or other suitable material, extending through the glass wall, and I usually provide a long seal 10 for protecting more or less of the leading-in conductor within the lamp. The electrode 5 is shown in this instance as being a small quantity of mercury. A leading-in conductor 8 connects with this electrode. Surrounding the lower end of the tube adjacent to and usually projecting a slight distance—say one-eighth of an inch—above the level of the lower electrode there is placed a thin band 9 of conducting material—such, for instance, as foil—and this is electrically connected by a conductor 13 with the leading-in wire 7. When the lamp is to be operated by alternating electric currents, it may be useful to place a conducting-band in similar relation to the other electrode and connect it with the leading-in conductor 8.

As already stated, the condensing and impurity-containing chamber 4 or its equivalent performs an important function in the operation of the lamp. As the lamp commences to operate heat accumulates and the increasing temperature appears to soon result in increased resistance on the part of the vapor-path. If the heat is not conducted away after the lamp has reached its proper working condition with the same rapidity that it is generated, the lamp may extinguish itself. The chamber 4 is therefore constructed with sufficient radiating-surface to get rid of the excess heat and keep the lamp in the proper condition. The chamber 4 need not, however, necessarily surround the electrode 2; but it may be located elsewhere and be of other form, provided it is out of the vapor path. The tube, properly shaped and prepared, is first thoroughly cleansed with acids, alkalies, and water. I have found it convenient to first dilute the tube with hydrofluoric acid and then wash with distilled water, and thereafter, if desired, it may be further washed by a bath of hot hydrogen. In case mercury is to be used for providing the conducting-vapor a small quantity of it is placed within the tube, and if the sulfid of mercury is to be used for forming the starting material a small quantity of that substance is added. Pure sulfur may be introduced instead of sulfid of mercury; but I have found that it is usually more difficult to secure the desired results with it than with the sulfid of mercury. The lamp is then sealed onto a suitable exhaust-pump 60, of any suitable character, through an exhausting-tube 61, and the process of exhaustion is commenced. Meanwhile artificial heat is applied to the tube—as, for instance, by a Bunsen burner 62, or an electric heater, or in some other convenient manner. After the free gases and air have been exhausted an electric current of higher potential is applied to the terminals of the lamp—as, for instance, by a system of circuits and apparatus—as shown diagrammatically in Fig. 2 and consisting of a transformer 40, the primary coil 41 of which is connected between the main conductors 14 and 15 and through any suitable form of circuit-interrupter 42. The secondary coil 43 has one terminal connected with the main conductor 14 and the other terminal through a suitable adjustable resistance 44ᵃ with the leading-in wire 7. In this manner induced high-potential currents may be applied to the terminals of the lamp, and the passage of this current through the lamp produces an effect somewhat similar to that noticeable in Geissler tubes. The operation of the exhaust-pump is continued, and a difference of potential approximately equal to that under which the lamp is intended to be operated is applied to the terminals of the lamp. As the lamp approaches completion it suddenly becomes intensely luminous by reason of the passage of a current of considerable quantity. If the higher-potential current employed is an interrupted current, it is desirable to reverse the terminals of the lamp with reference to that current one or more times, for the cathode is thereby readily heated to a very high temperature, which aids in driving off any occluded gases and impurities. A circuit-reverser 63 may be employed for that purpose.

The process of exhausting the lamp does not appear to remove the starting material, although apparently a different chemical compound is formed, and it is possible that some of the sulfur is thrown off or formed into some other combination and withdrawn from the tube. In any event sufficient of the starting material remains in the tube to permit the ready starting of the lamp when it is completed. The amount of sulfid of mercury to be introduced may be varied within wide limits. I have used in a lamp of approximately the dimensions hereinbefore referred to a quantity as small as may be taken upon the point of a pocket-knife and be plainly visible. Too much does not seem to exercise any very bad effect except retarding the process of exhaustion and possibly to blacken or coat the glass somewhat. In practice I usually find that after a time, notwithstanding the successive applications of high-potential currents and the running of the lamp with the low or moderate potential currents, little or no vapor is withdrawn from the lamp. The lamp may be continued on the pump for a greater or less time after this; but usually when the gases or vapors other than those employed in the operation of the lamp have been withdrawn therefrom the lamp is in condition to be sealed off.

While I have described the lamp more particularly with reference to mercury vapors, I desire it to be distinctly understood that I do not limit myself to those vapors nor to materials which at ordinary temperatures exist in the forms of solids or liquids, for permanent gases may be employed—such, for instance, as nitrogen. A convenient method to employ when gases are used is to first treat the lamp in the manner described with mercury vapors or any convenient vapor and then exhaust the mercury, and afterward introduce the gas or gases in the required amounts.

In certain other applications filed by me—for instance, Serial Nos. 11,605 and 11,606, filed April 5, 1900, and Serial Nos. 44,647, 44,648, and 44,649, filed January 25, 1901—claims are made upon certain of the subject-matters disclosed herein.

The invention claimed is—

1. The hereinbefore-described method of manufacturing electric lamps in which light is produced by the action of electric currents upon a vapor or gas which consists in heating the containing-chamber of the lamp by applied heat, exhausting the air and deleterious gases therefrom, heating the electrodes within the lamps by electric currents, introducing or forming the vapor or gas designed to constitute the light-emitting body and causing electric currents to traverse it and then closing the chamber substantially as described.

2. The method of manufacturing electric lamps in which light is produced by the action of electric currents upon a vapor or gas, which consists in introducing or forming into a containing-chamber the desired conducting vapor or gas and an additional substance yielding a starting material, heating the tube and exhausting air and vapor therefrom, causing a relatively high potential electric current to traverse the tube during a portion of the process of exhausting and then causing a current of considerable quantity and moderate electromotive force to traverse the

tube while continuing the process of exhaustion and thereafter sealing off the tube.

3. The process of manufacturing lamps adapted to produce light by the action of electric currents which consists in placing within an inclosing chamber a quantity of material adapted to afford a vapor which becomes light-emitting under the influence of electric currents of moderate potential and considerable quantity, adding thereto a quantity of material capable of imparting to the device the capacity of being traversed by electric currents, exhausting the atmosphere and impurities from the lamp and simultaneously heating the lamp by external heat and thereafter by the passage of electric currents.

4. The method of manufacturing lamps in which light is produced by electric energy acting upon a vapor or gas path, which consists in heating the elements of the lamp, exhausting the foreign substances therefrom, applying a sufficient difference of potential to the electrodes of the lamp during the process of exhaustion to cause the open space between the electrodes to be traversed by currents, varying the resistance of the lamp until currents of considerable quantity traverse the lamp at a moderate electromotive force, and thereafter sealing off the lamp.

5. In the process of manufacturing lamps having a vapor or gas path, the method of treating the electrodes during the process of exhaustion which consists in heating the electrodes by electric arcs formed at the junction of the gas or vapor with the electrodes.

6. The method of driving off occluded gases and foreign substances and producing chemical reactions within a lamp having a vapor or gas path, during the process of manufacturing the same, which consists in heating the electrodes within the lamp during the process of exhaustion by means of electric currents so applied as to render the electrode to be heated for the time being a cathode.

7. The method of manufacturing lamps, which consists in varying the density of the gas or vapor in the lamp while it is subject to the action of an electromotive force substantially the same as that with which the lamp is intended to operate, and also temporarily to a higher electromotive force, continuing such operation until the gas or vapor attains a standard luminosity and thereafter sealing off the lamp.

8. The method of manufacturing lamps having a vapor or gas path, which consists in applying a high alternating or interrupted difference of potential to its electrodes and gradually varying the resistance of the lamp by varying the density of pressure of the gas-path until a current of desired quantity traverses the lamp under the influence of the lower electromotive force with which the lamp is designed to operate.

Signed at New York, in the county of New York and State of New York, this 21st day of March, A. D. 1900.

RADIO CORPORATION of AMERICA

RADIOTRON U. V. 200

NEW VACUUM TUBE DETECTOR AND CASCADE AMPLIFIER

FOR

AMATEUR AND EXPERIMENTAL WIRELESS STATIONS

IN presenting **RADIOTRON U. V. 200** to the Amateur and Experimental field, the **RADIO CORPORATION OF AMERICA** offers a vacuum tube in which **QUALITY** is the predominating factor. U. V. 200 was designed specifically for the Amateur. It is a product of the great **RESEARCH LABORATORIES** of the General Electric Company. For the first time the Experimenter has at his disposal a supersensitive detector tube which will operate from one Standard Plate Battery. This tends towards economy and eliminates one of the objections to former types of tubes, some of which required from three to five standard plate batteries to furnish the requisite plate voltage.

RADIOTRON U. V. 200 is not only the best detector or "spark receptor" designed to date, but it is also an excellent *tone frequency amplifier* for magnification of the telephone currents in vacuum tube receiving circuits. It gives *unusual* results in standard amateur regenerative circuits.

A particularly good combination for radio-telegraphic and radio-telephonic reception is the use of **ONE U. V. 200** as a **DETECTOR** and two additional U. V. 200's as **TONE FREQUENCY AMPLIFIERS.** Such a combination can be worked from a *single 22½-volt plate battery.* Cascade tone frequency circuits (for radio-telegraphic reception), using one or two Model U. V. 200 tubes, are remarkably free from tube noises and from "singing" so characteristic of former gas content tubes when operated in this manner.

For extreme amplifications some experimenters prefer from three to six stages of tone frequency amplification. In such cases the combination of one Radiotron U. V. 200 as a *detector* and several stages of the Radio Corporation's Amplifier of the **PLIOTRON TYPE RADIOTRON U. V. 201**—give the best results.

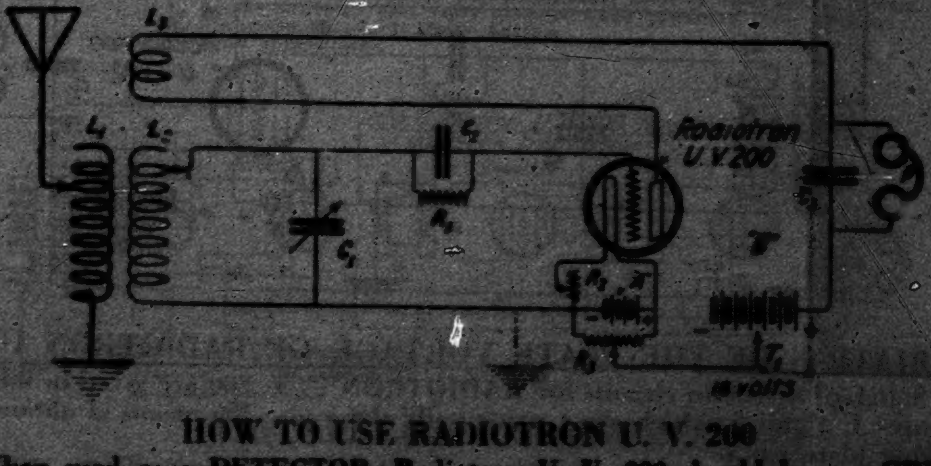

Fig. 1

HOW TO USE RADIOTRON U. V. 200

When used as a **DETECTOR**, Radiotron U. V. 200 should have a **GRID CONDENSER** of .00025 mfds., or thereabouts, connected in series with the grid. Many experimenters prefer a variable grid condenser which is of undoubted advantage in Regenerative circuits. In addition to the grid condenser one of the **RADIO CORPORATION'S** standard **GRID LEAKS** should be connected across the grid condenser, as shown in Figure 1.

To put Radiotron U. V. 200 into action, insert the tube in the **RADIO CORPORATION'S** Standard Vacuum Tube Socket.

Connect the "high potential" terminal of the tuner secondary to the grid (with a grid condenser in series).

Connect the other terminal of the tuner secondary to the negative terminal of the tube filament.

Connect the filament terminals to a 6-VOLT STORAGE BATTERY with a standard filament RHEOSTAT (of 6 to 10 ohms) in series. Make sure that all of the resistance of the rheostat is in the circuit before closing the circuit to the battery.

Connect the *Positive* terminal of a standard 22½-volt PLATE BATTERY to the "plate" of the tube, and the *Negative* terminal of the plate battery to the Positive or Negative terminal of the filament battery (with a telephone in series), according to the circuit used.

The voltage of the plate battery should now be capable of variation, either by means of an "A" *battery-potentiometer* (as in Fig. 1), or by means of taps brought from individual cells of a plate battery.

Set the plate battery tap at about 18 volts, and gradually increase the filament temperature by reducing the resistance at the filament rheostat, until signals from a distant radio station or from a locally excited oscillator circuit are clearly audible in the telephones.

Now *vary* the *plate voltage* and also the *filament temperature* until the maximum signal audibility is obtained.

NOTE that the *normal* filament current of RADIOTRON U. V. 200 is approximately 1 ampere, the maximum allowable current being about 1.1 ampere.

VOLTAGES IN EXCESS of 28 to 30 should not be applied to the plate circuit of RADIOTRON U. V. 200.

GRID LEAKS

Although tests indicate that in most cases the proper "leak resistance" for use with RADIOTRON U. V. 200 is approximately ½ megohm, this is not necessarily the correct value for all circuits. There are a number of factors in standard receiving circuits which govern the proper value of resistance, not the least of which is leakage through the insulation of the receiving apparatus. (Note R_1 in the accompanying diagrams.)

Resistance values of 500,000 ohms to 3 and even 6 megohms have been found to be of advantage. To get the best results with any vacuum tube detector the amateur should have at his disposal a small assortment of GRID LEAKS covering from ½ to 3 megohms for experimentation. The use of these leaks gives stability to tube circuits and often increases the signal audibility several times. The Radio Corporation's standard grid leaks are the most reliable yet put on the market.

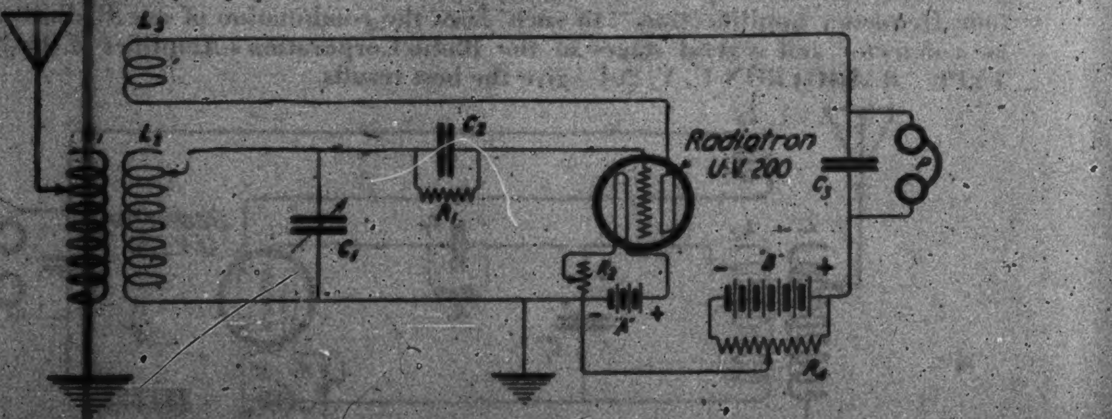

Fig. 2

VARIATION OF THE PLATE VOLTAGE OF RADIOTRON U. V. 200

Standard detection circuits for RADIOTRON U. V. 200 are given in the accompanying figures 1, 2 and 3, which show principally three possible means of obtaining a closely adjustable plate e.m.f.

In Figure 1, a standard 22½-volt "B" battery is tapped at the 12th cell giving approximately 18 volts. R-3 is the RADIO CORPORATION'S special "A" BATTERY POTENTIOMETER (which will be placed upon the market shortly) of approximately 200 ohms resistance. Through the voltage variation afforded by running the contact on R-3 along this resistance a very close adjustment of the plate e.m.f. can be obtained. When the "B" cell becomes partially exhausted the tap can be moved to the negative terminal of the last cell. The voltage thus supplied by the "B" cell, plus the additional voltage supplied by the resistance drop across the filament battery, gives the requisite variation of the plate potential for maximum signals.

Figure 2 differs from Figure 1 only in the method of varying the plate voltage. In this case, a "B" battery potentiometer R-4 of about 2000 ohms is connected across the "B" battery. This provides a very close adjustment of the plate e.m.f.

Fig. 3

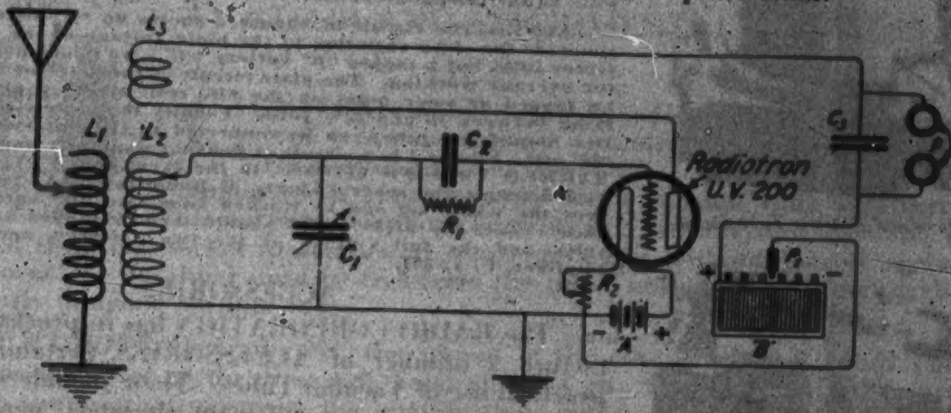

Figure 3 shows the same detection circuit with a tapped "B" battery, giving voltage variations by single cells through the tap P-1. Such batteries are now obtainable on the market. For most purposes a single cell variation of the plate voltage is satisfactory, but for extreme sensitiveness or maximum signal audibility, particularly when U. V. 200 is used as a detector, the Radio Corporation's "A" battery potentiometer is recommended.

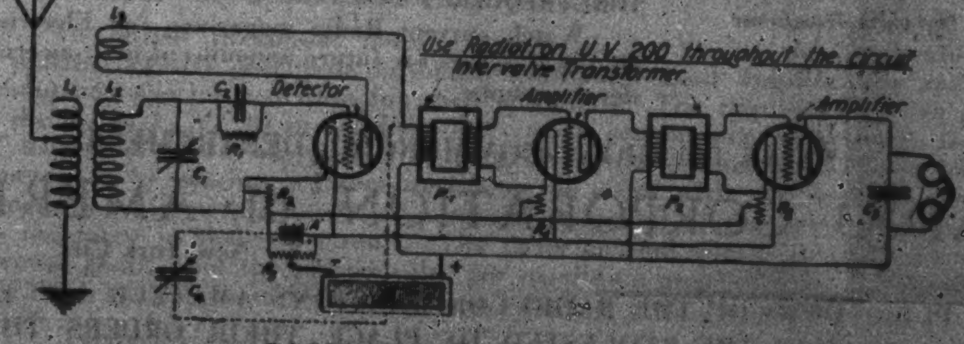
INTERPRETATION OF THE CIRCUIT DIAGRAMS

For those not familiar with radio-telegraphic circuits, interpretations of the notations on the diagrams, Figures 1, 2 and 3, are given below:

L-1. primary coil of tuning transformer.
L-2. secondary coil-tuning transformer.
L-3. "tickler" coil for regenerative amplification.
C-1. secondary variable condenser.
C-2. grid condenser (fixed or variable).
C-3. telephone condenser (fixed).
R-1. Radio Corporation's standard grid leak.
R-2. Standard filament rheostat (to carry at maximum 1.2 ampere).
R-3. Radio Corporation's special "A" battery potentiometer.
R-4. Standard "B" battery potentiometer, 2000 to 4000 ohms. (Fig. 2.)
A. 6-volt storage cell (any ampere-hour capacity from 40 up).
B. Standard 22½-volt plate battery.
P. head telephones.

Fig. 4



CASCADE AMPLIFICATION

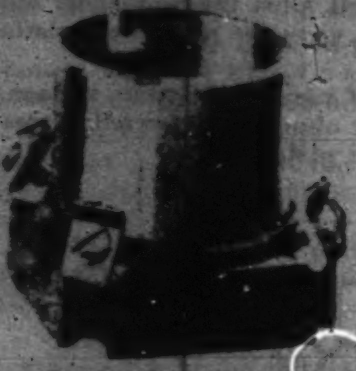
Amateurs and Experimenters are becoming accustomed more and more to use a detector tube with a 2-stage amplifier, for general communication. Such amplification is particularly desirable in radio telephony. It is in fact positively essential to secure satisfactory working ranges.

It is in this type of circuit that RADIOTRON U. V. 200 gives such marked results.

Figure 4 illustrates a detector-regenerative circuit with two stages of tone-frequency amplification. The notations on the diagram are explained below:

C-2. Radio Corporation's grid condenser of approximately .00025 mfds.
R-1. Radio Corporation's grid leak—½ to 3 megohms.
R-2. R-4, R-3, standard filament rheostats (6 to 10 ohms).
R-3. special "A" battery potentiometer (30 to 200 ohms).
A. 6-volt storage battery.
B. 22½-volt plate battery.
P-1. P-2, tone-frequency intervalve transformers.
C-4. bridging condenser (not necessary at short wave lengths).
P. telephones.
C-3. shunt telephone condenser (fixed or variable).

NOTE:—The circuit of Figure 4 shows an "A" battery potentiometer for close variation of the plate voltage of the first or detector tube, but a tapped "B" battery will give good enough results for average working. The plate circuit of the detector tube should be tapped at some point on the "B" cell, giving a plate voltage lying between 16 and 22½ volts. Usually the plate circuits of the two amplifying tubes can be connected to the full voltage of the "B" cell. Figure 4 is a circuit of unusual simplicity and one giving MARKED AMPLIFICATIONS. In the event that U. V. 200 is used as a detector and several stages of Radiotron U. V. 201 as amplifiers the whole set can be worked from two "B" batteries. The plate connection of U. V. 200 should then be tapped at 16 to 22½ volts, and the full voltage of the two batteries applied to the amplifier, U. V. 201.



Standard Vacuum Tube Socket

Standard Grid Leak

Intervalve Transformer

ACCESSORIES

The RADIO CORPORATION has in process of manufacture a number of ACCESSORIES pertaining to the practical use of Vacuum Tubes. These include special "A" battery potentiometers, filament rheostats, new forms of vacuum tube sockets, grid condensers of novel design, and many other devices which for obvious reasons cannot be announced at this time.

High grade workmanship characterizes the accessories. They are built for those who want the best at moderate cost.

New Amplifying Transformers for Radiotrons are in manufacture. These incorporate unusual features of design and give amplification markedly above that obtainable with existing types. We have some surprises in store for Experimenters.

LIST PRICES

RADIOTRON U. V. 200, gas content detector	$5.00
RADIOTRON U. V. 201, Pliotron amplifier	6.50
R. C. STANDARD VACUUM TUBE SOCKET	1.50
R. C. STANDARD GRID LEAKS, 30 values (from ½ to 6 megohms) each mounted	1.25
R. C. GRID LEAK UNIT only	.75
R. C. GRID LEAK MOUNTING	.50
TONE-FREQUENCY INTERVALVE TRANSFORMER	7.50

Watch current Radio magazines and Electrical Merchandise papers for future announcements concerning new developments.

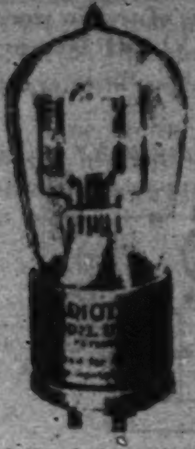
PURCHASERS OF THE RADIO CORPORATION'S AMATEUR AND EXPERIMENTAL DEVICES ARE REQUESTED TO PLACE THEIR ORDERS THROUGH THEIR LOCAL DEALERS. IN THE EVENT THAT THERE IS NO DEALER IN YOUR LOCALITY, WE WILL PUT YOU IN TOUCH WITH THE NEAREST ONE.

If you have not already seen our special bulletin for *Radiotron U. V. 201*, the Pliotron Amplifier, ask your Dealer for it or write us direct.

ON SALE BY

RADIO CORPORATION of AMERICA



RADIOTRON U. V. 201

A NEW AMPLIFIER OF THE PLIOTRON TYPE
FOR
AMATEUR AND EXPERIMENTAL WIRELESS STATIONS

COMPLEX amplifying circuits for the magnification of radio and tone frequency currents require an amplifying Vacuum Tube of *rigid* operating characteristics. There is an increasing demand among radio experimenters for a vacuum tube amplifier which will magnify the telephone currents in a radio receiving set and which can be shifted from one socket to another in a cascade outfit without loss of signal audibility. Moreover, the amplifier must be free from the tube "noises" accompanying the use of improperly designed vacuum tubes.

RADIOTRON U. V. 201, the second of the new series of Vacuum Tubes designed by the engineers of the Research Laboratory of the General Electric Company for the Radio Corporation, possesses the qualifications outlined above and it should be a part of every experimental radio receiving station. U. V. 201 may be used as a *detector*, or as a *tone frequency* or *radio frequency amplifier*.

In cascade radio frequency amplifying circuits, U. V. 201 can be adjusted to magnify without distortion. The use of such circuits is on the increase in amateur stations, particularly where long distance communication is desired on short wave lengths (200 meters or less).

As a *detector* the best results are secured from *Radiotron U. V. 201* with a *grid condenser* of approximately .0001 mfd. capacity and with a shunt GRID LEAK of ½ to 2 megohms, according to the type of circuit employed.

The normal plate voltage of Radiotron U. V. 201 is 40 volts, although increasing amplifications can be obtained at plate voltages up to 100. At 40 volts on the plate, the amplification constant varies from 6.5 to 8; at 100 volts on the plate, from 8 to 10. The output impedance varies from 15,000 ohms to 25,000 ohms at 40 volts on the plate, and from 10,000 to 15,000 with 100 volts on the plate.

The normal *filament current* for RADIOTRON U. V. 201 is approximately 1 ampere. The filament is designed for connection to the terminals of a 6-volt storage battery with a standard filament rheostat in series.

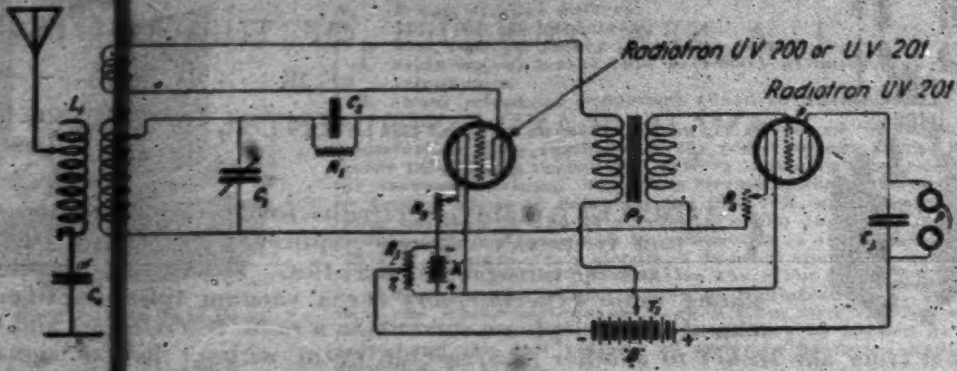
To obtain maximum amplification with U. V. 201 means should be supplied for placing negative potentials on the grid, although good amplification may be secured without any special provision for such potentials. The requisite negative grid potential for the use of U. V. 201 in *amplification circuits* can be secured by connecting a standard "C" battery of two or three volts in the grid circuit, shunted by a 200 to 400 ohm potentiometer, or by placing a 2 ohm resistance in series with the negative terminal of the filament and connecting the "low" potential" terminal of the tuner secondary to include this resistance in the grid circuit. The latter method usually provides the requisite grid potential results, but the proper value for maximum amplification is generally best found by trial and experiment, with a variable source of e.m.f. supplied locally.

IMPORTANT FACTS CONCERNING RADIOTRON U. V. 201

The Radio Corporation's gas content detector and amplifier tube, RADIOTRON U. V. 200, is in itself an excellent tone frequency amplifier, but it does not give the "power" amplifications obtainable from the Corporation's SPECIAL AMPLIFIER TUBE RADIOTRON U. V. 201. Thus, for devices requiring a considerable amount of energy for their operation, such as loud speaking telephones, Radiotron U. V. 201 should be used rather than RADIOTRON U. V. 200.

RADIOTRON U. V. 201 is, of course, applicable to all types of radio receiving circuits now in use among amateurs. Certain circuits in which U. V. 201 is especially desirable are depicted in Figures 1, 2, 3 and 4.

Fig. 1



DETECTOR AND ONE-STAGE AMPLIFIER CIRCUIT

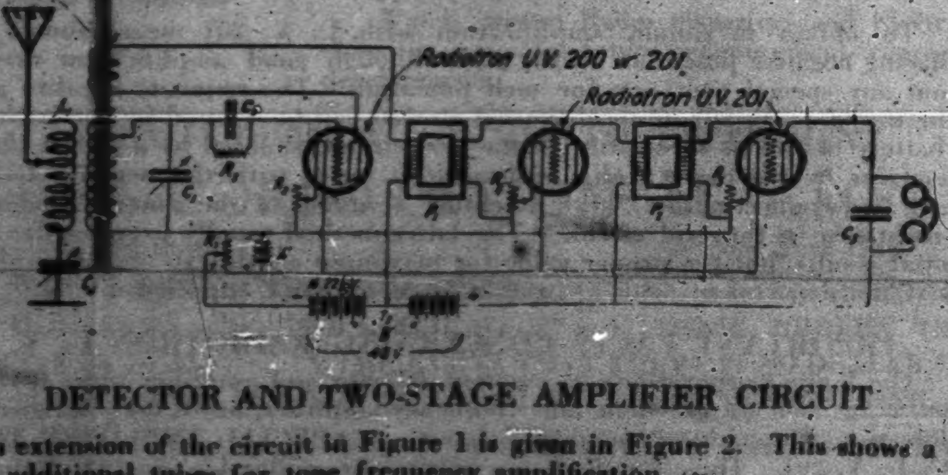
Figure 1 represents a detector and one stage amplifier circuit in which *one U. V. 200* or *one U. V. 201* tube is used for *detection* and one U. V. 201 as a *tone frequency amplifier.* Many experimenters prefer U. V. 200 as the detector, as it gives somewhat greater sensitiveness than U. V. 201 when used for the same purpose, but U. V. 200 requires a closer adjustment of the filament current and plate voltage than U. V. 201 for maximum signal audibility.

An explanation of the notations on the diagram follows:

-1, primary coil of tuning transformer.
-2, secondary coil-tuning transformer.
-3, tickler coil for regenerative amplification.
-1, secondary variable condenser.
-2, grid condenser (.00025 mfd. for U. V. 200 and .0001 mfd. for U. V. 201).
-3, telephone condenser (variable preferably).
-4, antenna series condenser.
-1, Radio Corporation's standard grid leak from ½ to 2 megohms).
-2, R-4, filament rheostats (6 to 10 ohms).
-3, Radio Corporation's special "A" battery potentiometer (300 to 200 ohms).
-1, tone frequency amplifying transformer.
P, head telephones.
A, 6-volt storage battery.
B, two standard plate batteries giving 40 volts.
-2, tap on the plate battery for applying from 16 to 22½ volts on the plate circuit for U. V. 200, if used.

NOTE:—If RADIOTRON U. V. 201 is used as the detector, the tap T-2 should be set to impress the full voltage of the plate battery on the plate circuit of the detector tube. For the use of U. V. 200 as a detector, the tap T-2 should be set at approximately 18 volts and the contact on the "A" battery potentiometer set at the position giving the loudest signals. If single cell variations of the plate voltage are obtainable, good results can be obtained without the "A" battery potentiometer. This potentiometer is not necessary when U. V. 200 is used as a detector.

Fig. 2



DETECTOR AND TWO-STAGE AMPLIFIER CIRCUIT

An extension of the circuit in Figure 1 is given in Figure 2. This shows a detector and two additional tubes for tone frequency amplification.

If RADIOTRON U. V. 201 is used throughout the circuit of Figure 2, the plate circuits of all three tubes may be energized at voltages from 40 to 100 volts. If RADIOTRON U. V. 200 is used as the detector, the tap T-2 should be set at approximately 18 volts. The "A" battery potentiometer R-3 may be dispensed with when RADIOTRON U. V. 201 is used as a detector as well as an amplifier, as mentioned above.

Tone frequency amplifying transformers are indicated at P-1 and P-2. Separate filament rheostats are shown for each tube, but if U. V. 201 is used for detection and for amplification, many amateurs will operate the filaments of all tubes through a single filament rheostat of the proper current carrying capacity.

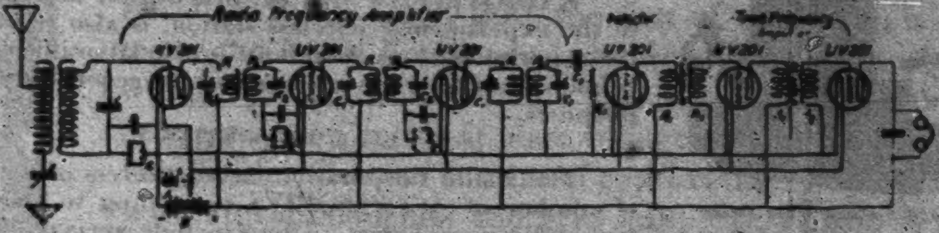


Fig. 3

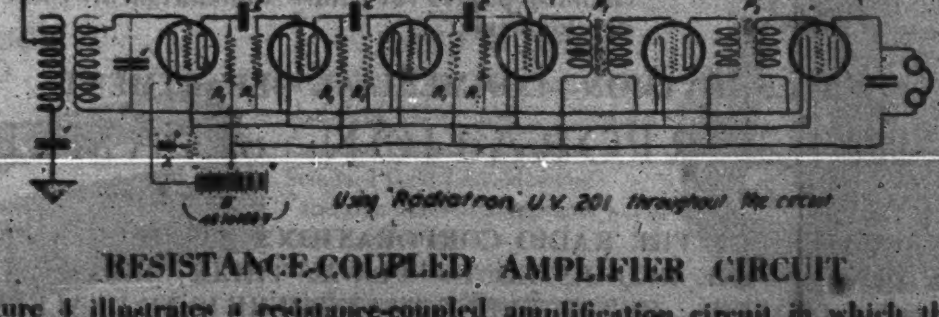
CIRCUIT FOR RADIO AND TONE FREQUENCY AMPLIFICATION AND DETECTION

Figure 3 indicates a complex detection and amplification circuit in which U. V. 201 will be found desirable. This circuit is made up first of three stages of radio frequency amplification, followed by one detector tube and two stages of tone frequency amplification.

In the radio frequency group, P-1, C-1 constitute the tuned primaries of radio frequency transformers, and P-2, C-2, the tuned secondaries, through which amplified radio frequency currents are impressed upon the grids of successive tubes. Negative grid potentials for distortionless amplification are obtained by the use of a "C" battery of 1 to 10 volts, shunted by a suitable potentiometer. The radio frequency currents in the grid circuit are by-passed around the potentiometer by a shunt condenser.

The grid condenser C-3 in series with the grid of the fourth tube (assisted by the GRID LEAK R-2) rectifies the amplified incoming radio frequency currents, and the output currents of the fourth or detector tube are further amplified by two stages of tone frequency amplification.

RADIOTRON U. V. 201 should be used throughout the circuit of Figure 3.



Radio Frequency Amplifier
Detector
Tone Frequency Amplifier
B Battery
Using "Radiotron" U.V. 201 throughout the circuit

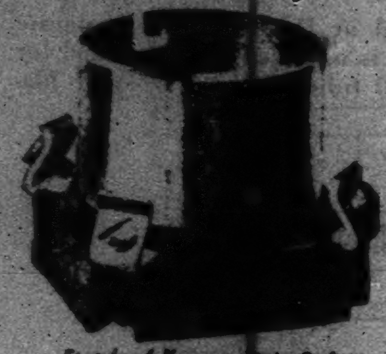
Fig. 4

RESISTANCE-COUPLED AMPLIFIER CIRCUIT

Figure 4 illustrates a resistance-coupled amplification circuit in which there are three stages of radio frequency amplification, the fourth tube being used as a detector. The tone frequency output of the detector tube is in turn amplified by two additional tubes in cascade.

For radio frequency amplification R-1 represents a coupling resistance of ½ megohm (The Radio Corporation's standard grid leak resistance may be used for this purpose.) R-2 indicates a GRID LEAK of approximately 2 megohms. P-1 and P-2 are suitable intervalve tone frequency transformers. A is a 6-volt storage battery of suitable current output, and B a plate battery providing from 40 to 100 volts for the plate. If a single filament rheostat such as R-4 is employed to control the filament current of all the tubes, the precaution should be taken to secure a rheostat of suitable current carrying capacity, allowing approximately 1 ampere for each tube.

There are numerous other circuits in which RADIOTRON U. V. 201 may be used with marked results.



Standard Vacuum Tube Socket

Standard Grid Leak

Intervalve Transformer

NOTE:—The Radio Corporation has in manufacture a new Amplifying Transformer designed specifically to fit the output circuit of RADIOTRON U. V. 201. The transformer incorporates certain novel features of construction and gives an over-all efficiency not yet approached by any other type. It is a device of superior workmanship and it is not to be confounded with intervalve transformers designed only to be sold at a cheap price. Delivery date will be announced later.

RADIOTRON U. V. 201, in addition to its usefulness to the experimental wireless station, is also recommended for experimental investigations in the laboratories of High Schools, Colleges, Universities and for general instructional purposes.

ACCESSORIES

The Radio Corporation has in process of manufacture a number of ACCESSORIES pertaining to the practical use of Vacuum Tubes. These include special "A" battery potentiometers, filament rheostats, new forms of vacuum tube sockets, grid condensers of novel design, and many other devices which for obvious reasons cannot be announced at this time.

High grade workmanship characterizes the accessories. They are built for those who want the best at moderate cost.

New Amplifying Transformers for tubes are in manufacture. These incorporate unusual features of design and give amplifications markedly above those obtained from existing types. We have some surprises in store for Experimenters.

LIST PRICES

RADIOTRON U. V. 201, Pliotron amplifier	$6.50
RADIOTRON U. V. 200, gas content dectector	5.00
R. C. STANDARD VACUUM TUBE SOCKET	1.50
R. C. STANDARD GRID LEAKS, 30 values (from ½ to 6 megohms) each mounted	1.25
R. C. GRID LEAK UNIT only	.75
R. C. GRID LEAK MOUNTING	.50
TONE-FREQUENCY INTERVALVE TRANSFORMER	7.50

ON SALE BY ☞

RADIOTRONS VACUUM TUBES *for* Amateur or Experimental Use

THE facilities and resources of the world-famous RESEARCH LABORATORIES of the General Electric Company have been concentrated upon the development and design of a new series of VACUUM TUBES for Radio Detection and Amplification. The RADIO CORPORATION OF AMERICA now offers to the Wireless Experimenter two distinct types, each adapted to a particular field of usage.

LIST PRICE
$5.00

RADIOTRON U. V. 200, the first of the series, is a Detector and Audio Frequency Amplifier of unusual capabilities, which operates from a single standard plate battery. Best detector action occurs at plate voltages between 18 and 22½ volts, with a filament current of approximately 1 ampere, and with a grid condenser and grid leak. U. V. 200 is particularly adapted to amateur regenerative circuits. A trial in such circuits will be the most convincing.

NOTE—A special "A" or filament battery potentiometer for close adjustment of the plate voltage of U. V. 200 will shortly be placed on the market by the Radio Corporation.

LIST PRICE
$6.50

RADIOTRON U. V. 201, the second of the series, is an unexcelled Amplifier of the PLIOTRON type, which may be used for Detection and for Radio or Audio Frequency Amplification. Normal plate voltage, 40 (two standard "B" batteries). Voltages up to 100 may be used on the plate with increasing amplification. Amplification constant, 6.5 to 8 at 40 volts on the plate, 8 to 10 at 100 volts on the plate.

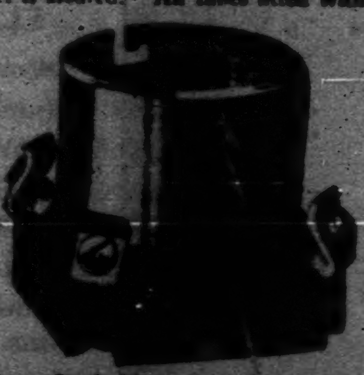
Note to Amateurs, Dealers and Jobbers

Radiotrons are manufactured by ultra-scientific methods laid down by America's foremost tube experts. No guess work—each tube bears the stamp of electrical manufacturers of world-wide reputation. A uniform product is assured. All tubes fitted with standard four-prong base. Filaments operate from 6 volt battery with rheostat.

Standard Grid Leak

LIST PRICES

Radiotron U. V. 200	$5.00
Radiotron U. V. 201	6.50
Standard Vacuum Tube Socket	1.50
Standard Grid Leak, Mounted 100,000 ohms to 6 megohms	1.25
Grid Leak Unit	.75
Grid Leak Mounting	.50
Audio Frequency Transformer	7.50



Standard Vacuum Tube Socket

A complete line of vacuum tube ACCESSORIES are now in manufacture and will shortly be available.

Dealers and Jobbers: We have an especially attractive proposition for you. Write us at once.

The Radio Corporation's tubes are covered by patents dated November 7th, 1905, January 15th, 1907, and February 18th, 1908, as well as by other patents issued and pending. Tubes licensed for amateur and experimental use only. Any other use will constitute an infringement.

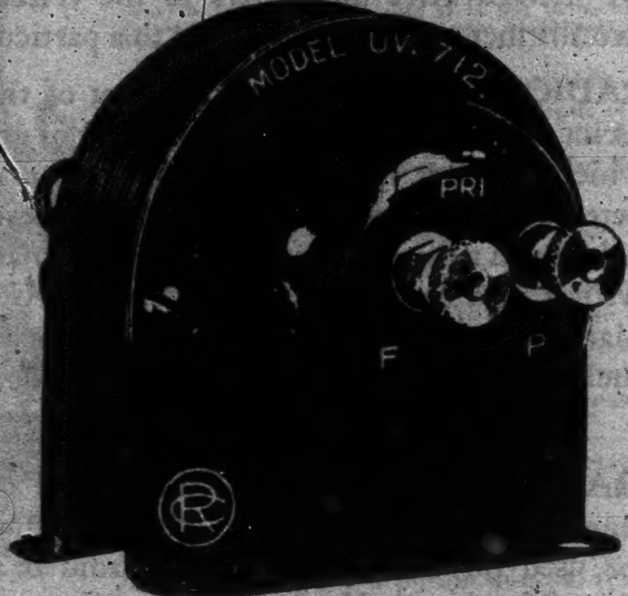
INTER-TUBE TONE FREQUENCY AMPLIFYING TRANSFORMERS

MODEL
U. V. 712
Price
$7.00



For Use With
Radiotrons
U. V. 200
and
U. V. 201

PHYSICAL CHARACTERISTICS

1. Totally enclosed.
2. Net weight 1 lb. 4½ oz.
3. Shipping Weight, 1 lb. 7 oz.
4. Overall length, 3⅞"
   Overall height 2¾"
5. Base area for mounting 2"x2¾"

ELECTRICAL CHARACTERISTICS

1. Ratio of Secondary to Primary Turns, 9/1.
2. Useful frequency range, 60/3000 cycles
3. Allowable current on each winding, 10 milliamperes.
4. Test voltage between windings and between core and windings, 300 volts at 60 cycles.
5. Terminal voltage limit of secondary winding, 300 volts.
6. D. C. resistance of windings: Primary 430 ohms, Secondary 5,100 ohms.
7. Impedance at 1000 cycles, (one milliampere);—

Primary with secondary open	19,000	ohms	(approximate)
Primary with secondary shorted	650	"	"
Secondary with primary open	1,100,000	"	"
Secondary with primary shorted	13,000	"	"

Model U. V. 712 is the only transformer designed specifically for use with Radiotrons.

GENERAL

It is a well known fact that for maximum amplification the characteristics of a tone frequency amplifying transformer must be such as to fit the output impedance of the preceding tube in a cascade amplifying set. There is an allowable variation of the constants of the transformer when loaded on the secondary by an amplifying tube, but nevertheless, the maximum signal is obtained from a transformer especially designed to *fit* the output impedances of the tubes with which it is used.

Prior to the introduction of the Radio Corporation's amplifying transformer, Model U. V. 712, amateur experimenters were compelled to employ intervalve transformers of various characteristics, none of which were designed specifically for the Radio Corporation's detector tube, Radiotron U. V. 200, and the amplifier tube, Radiotron U. V. 201. Transformer U. V. 712 not only has been designed to fit these vacuum tubes but special care has been taken to reduce the transformer losses to the lowest possible minimum.

The accompanying illustration shows the new amplifying transformer, Model U. V. 712, which in recent tests has proved most conclusively that it is superior to any on the market today. Transformer Model U. V. 712 has been designed and manufactured strictly on a quality basis. It is not to be compared with other types in which efficiency has been sacrificed to obtain compactness or to reduce manufacturing costs.

BRIEF OPERATING INSTRUCTIONS

In general a tone-frequency amplifier transformer should occupy the same position in the output circuit of a vacuum tube as the receiving telephone. The terminals P and F of transformer Model U. V. 712 may be connected to the binding posts which ordinarily are connected to the telephone receiver. The secondary terminals should connect to the grid and filament of the following tube of a multi-stage amplifier. Such a circuit using two stages of tone-frequency amplification is shown in Fig. 1. This circuit makes use of the detecting qualities of Radiotron U. V. 200 and the amplifying qualities of Radiotron U. V. 201.

In many receiving circuits, it is of advantage to connect a variable condenser from the plate of the detector tube to the negative side of filament, as shown by the dotted line at C_1. It is also frequently advisable to ground the point shown by the dotted lines at GND in order to obtain complete stability and eliminate inductive noises, although it is possible that noisy operation may be caused by rundown batteries, loose connections and faulty adjustment of the amplifier.

If the Radiotron amplifier U. V. 201 is used in the circuit of Figure 1, a plate potential of from 10 to 100 volts may be used, the resultant amplification increasing with the voltage. Forty volts, however, is sufficient for ordinary purposes. When

RECE

using 100 volts on Radiotron U. V. 201, the plate current is approximately 5 milliamperes and if this voltage is used, the polarity of connection to the telephone receivers should be such as to *increase* the magnetization of the permanent magnets rather than to decrease it. Using Radiotron U. V. 200, the Radio Corporation's [illegible] content bulb, as a detector, the plate voltage should be adjusted to some value between 18 and 22½ volts.

It is highly essential for the amateur to connect the transformer terminals as marked and as shown in Fig. 1. Transformer terminal marked G must always be connected to the grid of the next tube.

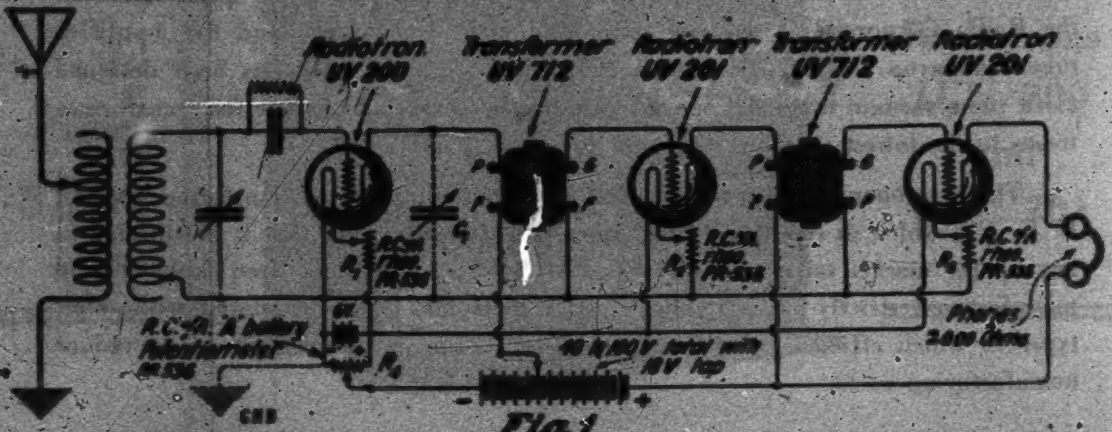


Fig. 1

In all radio amplifier circuits using Model U. V. 712 transformer, the insulation of all apparatus connected to the secondary must be as perfect as possible. Leakage from the grid to the filament of amplifier tubes through the socket, mounting, panel, wiring or otherwise, will decrease the amplification. The lead from terminal G should be kept reasonably short and in cascade amplifier sets adjacent transformers should not be mounted too close; a separation of at least 3 or 4 inches should be allowed.

R_1 R_2 R_3 are the filament control rheostats, P. R. 535, and R_4 is the special "A" battery potentiometer, P. R. 536, manufactured by the Radio Corporation.

The circuit diagram here given has the secondary F terminal connected to the filament rheostat on the side away from the filament. This puts a bias negative potential on the grid of Radiotron U. V. 201 which will have a value of approximately one volt providing a six-volt battery is used and the filament current is adjusted to the normal value of one ampere. Separate biasing batteries may be used if it is desired to get the absolute maximum of amplification. One or two dry cells may be connected in series with the grid circuit. These cells should be connected near to the low potential terminal of the secondary, that is next to one leg of the filament. The positive terminal of the battery should connect to one leg of the filament and the negative terminal to the tuner secondary.

NOTE: All Radio Corporation products are manufactured by the General Electric Company.

RADIO CORPORATION APPARATUS FOR EXPERIMENTAL USE

Radiotron Vacuum tubes and Accessories are manufactured exclusively for the Radio Corporation of America by the General Electric Company and are sold for amateur and experimental use only.

RADIOTRON U. V. 200, a "gas-content" detector designed specifically for amateur purposes	$5.00
RADIOTRON U. V. 201, an exceptional amplifier of the Pliotron type	$6.50

of power required to operate a loud speaker, and at the same time does not cause excessive drain from the plate battery. For head telephone reception, the higher plate voltages are unnecessary and very satisfactory results may be obtained at 40 volts. In this case a separate grid battery is unnecessary since the small bias obtained in the usual way by utilizing the voltage drop in the filament rheostat is sufficient. The purpose of this bias is to raise the input impedance of the tube to the point where it ceases to affect the terminal grid voltage, in other words to allow the total voltage induced in the secondary of the interstage transformer to be applied to the grid without loss in the windings of the transformer. A fraction of a volt is usually sufficient for this purpose.

The small elements and base of the UV-199 result in relatively low internal capacities, approximately 40 percent less than corresponding values for the UV-201. This feature is of particular

PETITION

To the Honorable Commissioner of Patents:

436

Your petitioner Irving Langmuir,

a citizen of the United States, residing at Schenectady,

in the County of Schenectady State of New York

whose Post Office address is % General Electric Co., Schenectady, N. Y.

prays that Letters Patent may be granted him for the improvement in

ELECTRICAL DISCHARGE APPARATUS AND THE PROCESS

OF PREPARING THE SAME (Docket No. 18,339)

set forth in the accompanying specification.

And he further prays that you will recognize Mr. Albert G. Davis, of Schenectady, New York, as his attorney, with full power of substitution and revocation, to prosecute this application, to make alterations and amendments therein, to receive the patent, and to transact all business in the Patent Office connected therewith.

Irving Langmuir

Cowgen

TO ALL WHOM IT MAY CONCERN:

BE IT KNOWN, that I, IRVING LANGMUIR, a citizen of the United States, residing at Schenectady, County of Schenectady, State of New York, have invented certain new and useful improvements in ELECTRICAL DISCHARGE APPARATUS, AND ~~AND~~ PROCESS OF PREPARING and Using THE SAME, of which the following is a specification.

N

The present invention relates to electrical vacuum discharge devices, and it comprises devices in which the electrical current is carried by negative charges called electrons, emanating from the cathode, independently of gaseous ionization such as occurring, for example, in the ordinary Roentgen tube.

My present invention comprises improvements in electron-discharge apparatus which make possible ~~having~~ a high load capacity and operation ~~operable~~ with the highest voltages. N The novel features of my invention will be pointed out with greater particularity in the appended claims.

N

Insert N

Figs. 1 and 2 of the accompanying drawings, Fig. 2 being a partial view, illustrate two types of discharge devices embodying my invention; Fig. 3 is a fragmental view showing a cathode construction, and Figs. 4 and 5 are diagrams of electrical systems illustrating certain applications of my electron discharge tubes.

In order to distinguish electron discharge devices made in accordance with my invention from the prior art, I will explain briefly the character of a pure electron discharge as distinguished from a discharge through ionized gas. In a Geissler tube, and in a Roentgen or Crookes tube the conduction of current is accompanied by and depends upon gas ionization. Without a certain minimum amount of gas a Roentgen ~~an [illegible]~~ X-ray tube ceases to operate and as this minimum is approa

N

the resistance of the tube steadily increases.

Sub. N. 2

1/3

Scientific research has shown that under certain very carefully controlled conditions with extremely low current values of the order of magnitude of .01 of one milliampere or lower and at low voltages, well below 200 volts, an electrical discharge current may take place in an evacuated space between a heated cathode and a cooperating anode without causing the residual gas to take part in the conduction of current. This effect also takes place in a vacuum when an unheated electrode consisting of certain materials, for example, potassium, is subjected to the influence of light, particularly, to ultraviolet rays. The discharge current is carried by negative charges called electrons, which pass through the vacuous space under the influence of the impressed voltage. In the presence of gas these electrons, when moving with proper velocity, collide with gas molecules and give rise to gas ionization which completely changes the phenomena accompanying the discharge. The gas molecules are split up into electrons and larger and more slowly moving positive ions. The positive ions take part in the conduction of current, giving at first erratic readings on measuring instruments connected in circuit. As gas ionization continues at higher voltages a blue glow may appear. The cathode under these conditions is ~~electrically~~ disintegrated, technically it is "sputtered", which causes its rapid destruction. The bombardment of the cathode by positive ions also causes heating of the cathode.

N

4 N 3

Insert N. 3

9

N

The phenomena above described as being characteristic of devices involving gas ionization are taken advantage of in an incandescent cathode device with three electrodes known as the "Audion". This device has been used as a receiver for radio-telegraphy and depends in its operation upon the rapid change of the

N

discharge current when gas ionization begins. This point depends upon various accidental conditions which cause such irregularities in the operation of various devices apparently identical that sometimes only one of a considerable number can be used. Ordinarily the gas ionization in the Audion begins *to be important* somewhere between 20 and 30 volts. (9) N 5 ~~With the exception of the X-ray tube described in an application, Serial No. 366,540, filed May 2, 1913, no prior~~ *no prior hot cathode* devices are known to me operating with currents as great as about ~~6~~ milliamperes with voltages as high as about 200 volts. N 5 (6) N 6

Insert N 5

Per ...

Insert N 6

In devices made in accordance with my invention gas ionization is either entirely absent or is negligible and a discharge takes place which is distinct in its characteristics from the described discharge taking place in an ionized gas.

The cathode is not heated by the discharge itself. ~~Blue glow~~ *glass fluorescence* and in fact all *readily* visible indications of a discharge are *ordinarily* absent. (8) N 7 ~~Glass fluorescence is absent in a device operating with a pure electron discharge. The discharge current passing through a given space with the cathode at a sufficiently high temperature varies directly with the 3/2 power of the impressed voltage. The discharge is independent of the vacuum, providing the pressure is below the minimum at which gas ionization by collision will take place.~~ As distinguished from discharges in the presence of positive ionization, the pure electron discharge is characterised by regularity and reproducibility with given conditions. (82) N 8 ~~and operating independently of positive ionization~~

Insert N 7

Insert N 8

Devices made in accordance with my invention may be used for various technical purposes, such as relaying and detecting currents, producing oscillations and rectifying alternating currents (7) N 9 with currents thousands of times greater than the ~~minute~~ currents at which the devices ~~above referred~~

Insert N 9

of the prior art ~~to~~ were operable without substantial positive ionization

~~The gas occluded in metals and driven out by the electrons impinging thereon appears to be especially liable to ionization, as it may be observed that gas eliminated from the anode even when below the pressure permissable for residual gas produces the effects accompanying gas ionization. In fact, gas thus eliminated from the anode may not even produce a difference in the reading of a McLeod vacuum gage and yet produce ionization effects.~~

~~The application filed by Wm. D. Coolidge describes a novel electron discharge apparatus adapted particularly for the production of X-rays which is operable with a high energy input during the evacuating process. I have found that deleterious gases may be removed by electron bombardment even at a low temperature, which is advantageous as the device may not be adapted to receive a high energy input, or current of sufficiently high voltage may not be available.~~

Before describing the method of preparing my new type of apparatus, I will describe the structure of the apparatus illustrated by Figs. 1 to 3.

As shown in Fig. 1 the various parts of the apparatus may be mounted in a tube, or envelope ~~globe~~ 1, upon a pedestal 2, similar to the mount used in incandescent lamps. The cathode 3 is centrally located and may consist of a short straight filament not shown in Fig. 1, but indicated by the position of terminals 5, 6, and shown plainly in Fig. 3. The cathode shown in Fig. 2 consists of a thin V-shaped conductor. Either form may be used, the particular form of cathode being ordinarily determined by convenience of construction. Preferably the cathode conductor is held taut by a spring 7 to avoid contact of the cathode conductor with the grid by sagging when the metal is expanded at a high temperature. The filament 3 is mounted between two oppositely disposed supports, 9, 9', in this case constituting a closed loop, which may consist of insulating material, such as glass or quartz, but in some cases may to advantage consist of metal. Upon this frame-work is wound a ~~wire~~ discharge-varying conductor 10, ordinarily called a grid. The turns of the wire are closely adjacent to each other and are also very closely adjacent to but are out of contact with the incandescent cathode. By means of this grid 10 potential may be applied to exert a static control upon the movements of the electrons. A negative potential applied on the grid reduces the flow of current from cathode to anode in proportion to the degree of negative charge. A positive grid potential assists and directs the flow of current from cathode to anode in proportion to the degree of its charge.

The supporting framework for the cathode and grid is attached to a rod 11, mounted upon the stem of the tube. Adjacent to the cathode and grid is the anode 12 which in the present case has been indicated as consisting of a wire strung in a zig-zag manner over hooks 13 upon fork-shaped supports 14 and 15, but it is not necessary that it should assume this particular form. Both anode and grid preferably consist of tungsten, but other refractory metals may be used. By constituting the anode a continuous conductor it can be conveniently heated by passage of current during evacuation of the device and for this purpose is attached to leading-in conductors 16 and 17. The grid is indicated in Fig. 1 as being attached to leading-in conductors 18 and 19 at opposite ends, although but one terminal is ordinarily necessary.

In some cases it is desirable to use a plate-shaped anode; Fig. 2 illustrates such an arrangement suitable particularly for rectifying alternating current. The tube itself and other extraneous parts have not been shown in Fig. 2, as they are similar to Fig. 1. The cathode construction has already been referred to and the anodes 20 and 21 also preferably consist of tungsten and may be connected electrically with each other. Current connections are made by conductors 22, 23, the supports 24, 25 being merely indicated. 15

Insert N 10 WH

For the evacuation of the device the glass walls of the tube are carefully heated to as high a temperature as the glass will stand without softening and in general the most approved methods of incandescent lamp exhaust are used. The evacuation of the tube preferably while still heated is carried out by means of a suitable evacuating means, for example, a Gaede molecular pump, which removes vapors as well as gases. Chemical evacuating means such as electrically vaporized calcium or magnesium may also be used. Either before or during the evacuation the anodes may be heated, especially when the anodes are to be run at elevated temperature during the normal operation of the device. In this case the temperature is preferably carried close to ~~the melting point of tungsten.~~ brilliant incandescence. In the case of the structure shown in Fig. 1, the heating may take place by passing an electrical current through the wire 12. ~~In fact, the~~ The heating may take place in a suitable vacuum furnace, the temperature preferably being ~~close to the melting point of tungsten, or whatever refractory metal constitutes the anodes.~~ raised to 1800°C or even higher

I.L. WHH

I.L. WH Insert N 11

Subst N 12

~~However, heat alone will not remove all the gas liberated by the electron discharge, but this gas is driven out even at ordinary temperatures by the discharge itself. The discharge appears to affect especially the surface of the metal. Heating is a valuable aid in bringing gases from the interior of the metal body into the sphere of action of the discharge but may be omitted when the devices are not heated during normal operation.~~

The bombardment is carried out when the evacuation

Expunge

The bombardment is carried out when the evacuation has proceeded to a high degree by applying a potential between the cathode 3 and the anode 12, Fig. 1, the value of which depends upon the character of the device. Care should be taken to use a voltage below that at which a blue glow appears as this indicates harmful gas ionization, and as already pointed out, sputtering and disintegration of the cathode accompanies or closely follows the blue glow phenomenon. The pump should be constantly operated to remove the gas. After the removal of the gas thus driven out the voltage impressed between the cathode and the anode, or anodes, as the case may be, is increased thereby driving out more gas. This process is continued step by step with a progressively higher voltage, the final voltage depending upon the character of the apparatus. In most cases the final voltage should be materially higher than the voltage at which the device is to be used in actual service. However, in the case of devices that use exceedingly high voltages, such as 50,000 volts or even higher, substantially all the gas may be removed from the anode without resorting to voltages higher than the normal operating voltage. In the case of a plate-shaped anode which cannot be readily heated by passage of current, the discharge voltage may be chosen great enough to convey sufficient energy to the anode to raise its temperature to redness or even higher, when the device is to be used with a discharge current adapted to heat the anodes. ~~In the case of a device in which the anode normally operates at low temperature bombardment without heating may suffice.~~ After the metal has been freed from occluded gas, reabsorption of gas will not readily take place even though it is exposed to the air or other gases. For example, anodes thus treated may be removed to other apparatus which then may be evacuated with less ~~without further~~ electron bombardment of the anode or anodes.

The evacuation of the device should be preferably carried to a pressure as low as a few hundredths of a micron or even lower, but no definite limits can be assigned. The residual gas pressure should be below the value at which ionization by collision will take place at the given working voltage and current, with its accompanying phenomena of blue glow, disintegration of the cathode, and so forth. When the cathode and anode are located in close proximity and the discharge confined to the region between the same, the per-~~[illegible]~~missible pressure is higher than when the cathode and anode are at some distance. It is also true that when the anode has been carefully freed from gas, residual free gas, even if present in a sufficient amount to cause some gas ionization when the apparatus is first started, does little harm, as it is quickly removed by the gas clean-up effect when the device is operated.

Electron discharge apparatus thus provided with a gas-free pretreated anode or anodes, may be constructed to handle currents at a very high voltage by proper mechanical design of the parts subjected to static strains, suitable proportioning of the parts and so forth as described, for example, in my ~~copending~~ application Serial No. 775,604 filed ~~concurrently~~ herewith ✓ N. 3

Insert N. 3

The ~~[illegible]~~ asymmetric conductivity existing between the heated and unheated electrodes of a device of the character described may be utilized for various technical purposes. Reference has already been made to the rectification of current. As shown in Fig. 4 an electron discharge tube may be used for detecting electromagnetic waves in radio-telegraphy. As shown in this Fig. 4 the grid g and heated cathode c of an electron discharge tube 24 are connected respectively to the terminals of the secondary of a transformer 27, the primary of which is included in the antenna circuit 28. The antenna is grounded through a condenser 29 in the usual manner. The cathode *c* is heated by a local source of energy, as battery *B*. A battery 30 in the grid circuit 31 has its negative terminal connected to the grid *g*. A condenser 32 shunts the secondary of the loosely coupled transformer 27. The inductance of the transformer and the capacity of the condenser are adjusted to make the receiving circuit resonant to the frequency of the oscillations to be received. The oscillations set up by the incoming signals are superimposed upon the negative grid potential and causes a variation of current transmitted between cathode *c* and anode *a* by a local source of energy such as a battery 33 included in the local or plate circuit 34,35, of the discharge tube. This circuit is connected to an ordinary telephone receiver 36, preferably shunted by means of a condenser 37, whereby the signals are detected.

Fig. 3 illustrates how an electron discharge tube may be used in a system for producing alternating current from direct current. The anode *a* and cathode *c* are connected respectively to conductors 38,39, one of which includes a local source of energy, such as a battery 40. The terminals of these conductors are connected to an inductive coil 41. The cathode and grid *g* are also connected respectively by conductors 39 and 42 to a second inductive coil 43 which may be in a variable inductive relation to the coil 41. As soon as a flow of current starts in the plate circuit 38,39, current is induced in the coil 43 of the grid circuit 39,42. When by reason of this current the grid becomes negatively electrified, the flow of current in the plate circuit is reduced, and as the plate current decreases the grid electrification changes to positive, which again allows the current in the plate circuit to increase. These changes take place with a frequency depending on the

electrical characteristics of the circuits. Across the grid circuit 39, 42, of the discharge tube, in some cases is connected a condenser 44, the capacity of which may be varied to control the frequency of the oscillations set up by the system. The oscillations may be transformed to higher or lower voltage by a transformer coil 45 to the terminals of which are connected transmitting conductors 46, 47. The system shown in Fig. 5 is described and claimed in a copending application, Serial No. 772 997. filed October 29, 1913.

UNITED STATES PATENT OFFICE

In re Application of :
IRVING LANGMUIR, :
Serial No. 795,610, : ELECTRICAL DISCHARGE APPARATUS AND THE PROCESS OF PREPARING THE SAME
Filed Oct. 16, 1913, :
Room No. ------- :

Honorable Commissioner of Patents,

Sir:-

It is requested that the following amendment be made in the above-entitled application:

Page 3, line 8, cancel "prior" and substitute - hot cathode -

Line 21, after "temperature" insert - so as to give a sufficient electron emission for a given voltage -

Add the following claims:

Sub. 15

~~6.~~ An electrical discharge device comprising a gas-tight envelope, an electron-emitting cathode, and a discharge ~~varying~~ conductor ~~and~~ a cooperating anode, the space in said envelope being evacuated to below the pressure at which deleterious gas ionization takes place constituting a device ~~in which~~ ~~as evidenced by the fact that~~ the current passed over ~~the normal~~ a working range of voltage and temperature varies with the 3/2 power of the impressed voltage for voltages above a minimum voltage depending on the electron emission of the cathode.

a'

~~7.~~ An electrical discharge device comprising a gas-tight envelope, an incandescent cathode, and a gas-free anode, the space in said envelope being evacuated to below the pressure at which deleterious gas ionization takes place, ~~as evidenced by the fact that~~ the current passed by said device

~~over the normal~~ a working range of voltage and temperature ~~varies with the 3/2 power of the impressed voltage for voltages above a minimum voltage depending on the temperature of the cathode.~~

11. ~~6.~~ A high vacuum electron discharge device comprising an envelope, an incandescent cathode, and ~~and~~ an anode, the space in said envelope being evacuated to such degree that the passage of current produces no appreciable positive ionization when the ~~impressed~~ voltage is as high as 200 volts. N¹⁶ follows

A. F₁ E ~~Insert~~ C

15 ~~8~~ ~~7.~~ ~~An electrical discharge ~~amplifying~~ device, comprising a gas-tight envelope, an electron-emitting cathode, an anode deprived of ionizable gas and a discharge controlling conductor, the space in the envelope being evacuated to a pressure not substantially in excess of a few hundred thousandths of a millimeter of mercury, said device being characterised by the fact that the current varies with the 3/2 power of the impressed voltage when the electron emission of the cathode is above a minimum value for a given voltage.~~

E

Sub N¹⁶

--------o--------

The above claims are added to more completely protect applicant's invention.

Respectfully submitted,

Albert G. Davis

Attorney for Langmuir.

Paper No. 3
All communications respecting this application should give the serial number, date of filing, title of invention, and name of the applicant.

DEPARTMENT OF THE INTERIOR
UNITED STATES PATENT OFFICE
WASHINGTON Feb. 28, 1914.

Mr. Albert G. Davis.
C/o General Electric Co.,
Schenectady, New York.

Please find below a communication from the EXAMINER in charge of the application of

Irving Langmuir, S. No. 795,610, filed Oct. 16, 1913, Electrical Discharge Apparatus and the Process of Preparing the Same.

Thomas Ewing
Commissioner of Patents.

The amendment filed Dec. 29, 1913, has been made of record.

The following references are made of record:

Friedrich, 1,083,677, Jan. 7, 1914, 250 - 35,
Fleming, 803,684, Nov. 7, 1905, 250 - 8,
German patent 254,588 of 1912, (one sheet), 250 - 271
German patent 259,246 of 1913, (one sheet), 250 275, and the book
"Notes on X-Lights", by Rollins, Boston, 1903.

The reference to application No. 767,549, in lines 7 and 8, page 3, should be canceled unless filed by applicant. Line 10, page 4, should be corrected accordingly.

Page 8, lines 22 and 23, complete data for the application referred to should be supplied. Also see lines 8 and 9, page 10, in this connection.

Note 97, page 105, of Rollins describes a method of evacuating a tube in which a moderate current is sent through the tube for some hours during the pumping process. Claim 1 is rejected as being fully anticipated by the disclosure in Rollins.

Claims 2, 3, 4 and 5 are rejected on the same reference and ground as claim 1. The moderate voltage described in Rollins is "adapted to" perform the function recited in these claims. The reference also states that as the vacuum increases it is necessary to increase the operating potential, and this increase could be carried on to any point desired. Increasing the voltage to a point in excess of the operating voltage is a mere carrying forward of the method disclosed in Rollins. Furthermore, there is nothing to indicate that the process was not continued to such a point in Rollins. This method is also mentioned in the resume of known methods of evacuation found in Freidrich, cited.

Claims 6, 7 and 9 are rejected on Freidrich, cited, attention being particularly directed to lines 121 to 125, page 3 of this reference. It is noted that the matter beginning "as evidenced by" in no way distinguishes from the reference. If applicant's device is an improvement over the reference he should define the difference by structural limitations.

Claim 8 is rejected on either of the German patents cited, each of which discloses an incandescent cathode. There is no invention in reducing any discharge device having an incandescent cathode, as these German patents, for example, to any degree of vacuum in view of the Rollins note and Freidrich, cited.

The claims are each rejected.

Wm A Kinnan
Examiner, Division XVI.

ELECTRICAL DISCHARGE APPARATUS AND THE PROCESS OF PREPARING THE SAME.

Schenectady, N.Y., April 30, 1914.

Hon. Commissioner of Patents,

Sir:-

In response to the Official Action of February 28, 1914, please amend as follows:

Page 3, lines 6 to 8, cancel "With the exception of the X-ray tube described in an application, Serial No. 766,549, filed May 8, 1912, no"

Line 8, before "not" insert - No prior -

Page 4, cancel the sentence beginning with "The application" line 10 and ending with "process" line 13.

Page 8, line 22, after "Serial No." insert - 795,609 -

Line 23, after "filed" insert - concurrently herewith -

Page 10, line 9, after "Serial No." insert - 797,987 -

Same line, after "filed" insert - October 29, 1913 -

Pen

Claim 1, line 5, after "anode" insert - ~~and an impressed voltage below the value at which considerable gas ionization occurs~~ -

Claim 6, lines 5 and 6, cancel "as evidenced by the fact that" and insert - constituting a device, in which -

Line 6, after "current" insert - passed -

Claim 7, line 5, after "place" insert a comma

Same line, cancel "as evidenced by the fact that"

Same line, after "current" insert - passes by said device -

Line 7, cancel "varies" and substitute- varying-

Add the following claim:

Pec N

Pec C

~~13.~~ 16 The process of removing ionisable gas from a conductive body which consists in producing an electron discharge substantially independent of gas ionization, directing said discharge upon said body in a vacuum, while maintaining the energy of said discharge below the value necessary to heat said body to incandescence and coincidentally removing the gas thereby ~~thereby~~ disengaged from said body.-

Pec D

Insert C³

Applicant's attorney fully realizes the difficulty the Examiner finds in distinguishing the boundaries of the present invention over disclosures of a highly exhausted X-ray tube. Such differences are present, however, in a very real sense. No matter what language may be used in describing the vacuum of devices such as shown in the Friedrich patent 1,083,677, the fact remains that the operation of theFriedrich tube must depend on the presence of gas. In fact, Friedrich says, (page1, lines 50 to 56) "The regulating device should not be on the outside of the tube but should be located within some near the center so that the gases absorbed by the regulator may be easily liberated for the purpose of forming a passage for the current" and again (page 4, lines 31 to 33) referring to the heating of the asbestos, that "gases are expelled for the purpose of establishing a passage for the high potential current between the electrodes". A vacuum discharge not provided with some such electron-emitting means, as an incandescent cathode, must depend on gas ionization to furnish current carriers. Hence, clean-up of gas by operating the device can never reduce the pressure below the point at which gas is ionizable and for this reason an X-ray tube of the nature described by Friedrich or Rollins cannot be used to practice the method claimed. For this reason the gas can not be removed from the anode by bombardment to the degree necessary for a device which operates without positive ionisation.

The difference between the pure electron discharge and a discharge in which positive ions are produced have already been discussed in the specification. A further discussion may not be out of order. The Examiner either does not consider the limitation "electron-emitting cathode" a structural limitation or considers the vacuum to differ merely in degree over German patents Nos. 254,588 and 259,246. These patents to be sure do disclose a hot cathode but evidently describe devices depending on gases for their operation (lines 42-44, patent 254,588 and lines 58-59, patent 259,246), in fact, the subject matter of the invention is the provision of a source of vapor for the operation of the device.

The Fleming patent 803,684, discloses a rectifying detector for wireless telegraphy, which contains a heated carbon filament. Fleming merely states that "a very high vacuum should be obtained" but gives little information as to the characteristics of the device. Applicant claims not merely to have improved on the Fleming device, or any other hot cathode device, but to have produced a fundamentally new device which operates independently of gas conduction or ionization. Prior investigators were unable to enter this region of low vacuum, in which the permissable pressures are one-thousandth as great as Rollins "millionth of an atmosphere". (Notes on X-Lights cited by the Office).

Nine years before the filing of his patent application Fleming published a paper in the Phil. Mag. Vol. 42 (1896), page 52, describing his hot cathode device. He gives a great many current readings. These readings never exceed a few milli-amperes, usually less than one milli-ampere. The voltages used necessarily were very low - from .34 to 26.8 volts. As pointed out in the specification, gas ionization at low voltage is very slight. Inasmuch as it was impossible to free carbon from gases under the conditions open to Fleming, higher voltages would inevitably produce blue glow and the various other phenomena accompanying positive ionization.

Richardson, a prominent worker in the field, describes in the Proc. Roy. Soc. LXXI. pp.415-418 (1903) widely variable results. He reports an electron emission-

For platinum from 10^{-10} to 10^{-3} amperes per sq.cm. of surface.
For carbon from 10^{-8} to 2 amperes per sq.cm. of surface.
For sodium from 10^{-11} to 2×10^{-2} amperes per sq.cm of surface.

Wilson Phil. Trans. (1904) p.243, or Proc.Roy.Soc. Vol. 72, p.272, found that pretreating the platinum the current was reduced to $\frac{1}{250,000}$ of the values assigned by Richardson. With carbon he confirms the results of Richardson. He concludes that "It is probable that a pure platinum wire heated in a perfect vacuum would not discharge any electricity at all, either positive or negative, to an extent appreciable on a galvanometer." Wilson's results lead him to believe that the "negative leak" as he called it, "is due to the presence of hydrogen or possibly some other substance in the wire".

Pring and Parker later [Phil. Mag. 23,192,(1912)] showed that by careful purification of the carbon and an improvement of the vacuum very much lower readings were produced. With a potential difference of 330 volts, at a cathode temperature of 1800° they got the low value of 1.5 x 10^{-9} (.000,000,001,5 amperes) per sq. cm. of cathode surface, and at 2000° with a voltage of 200, a current of 4 x 10^{-7} amperes. They observed that the current "increased only very slightly with the temperature above 1800°". From these figures they conclude.

> "These results clearly show that the large currents hitherto obtained with heated carbon cannot be ascribed to the emission of electrons from carbon itself, but they are probably due to some reaction at high temperatures between the carbon or contained impurities and the surrounding gases which involves the emission of electrons."

Pring and Parker conclude that the large currents found by Richardson must be erroneous as by the formula announced by him the emission at 2000° should be about 100,000 amperes instead of 4 x 10^{-7} as found by them.

The large currents noted by Pring and Parker when the vacuum is poor suggest a possible explanation of the results obtained by Richardson and Wilson using a carbon cathode. In this connection a later paper by Pring ~~and [illegible]~~ is of interest (Proc. Roy. Soc. 89,344) In the conclusion the following statements occur:-

> "It has been shown that a still further large reduction in the ion[illegible]ought about by eliminating further the absorbed gases from the carbon."

> "It is clear from these results that thermal ionisation ordinarily observed with carbon is to be attributed to chemical reaction between the carbon and the surrounding gas."

Applicant preferstungsten to carbon because tungstencan be rendered gas-free so much more completely.

Fredenhagen in Physik Zeit January 1, 1914, P. 19 and January 15, 1914, P. 65, discusses the probable effect of chemical reactions on the electron emission of hot bodies or illuminated metal surfaces and expresses the theory that the effect is due in part at least to residual gases in the evacuated space and evidently believes that were the gases all removed the effect would cease.

Greinacher (Verh. d. D. phys. Ges. 15,797, 1913) and Pohl & Pringsheim (Phys. Zeit 14,1112, 1913) express a similar view.

In a recent paper (Fortschritte auf den Gebiet der Roentgen strahlen Bd 18, 256) Lilienfeld & Rosenthal describe an X-ray tube which they believe to have so completely evacuated that the conduction of current had become independent of the degree of vacuum (i.e. of the residual gas). They say: "And it is to be expected that finally a vacuum will be reached in which the transport of electricity will be entirely carried by negative electrons emitted from the incandescent cathode. As an actual fact the reverse takes place as established above." A consideration of the operation of the device makes it clear that the authors were mistaken as to the degree of vacuum. One of the tests of positive ionization is conductivity in the space as evidenced by current flowing between two unheated electrodes in the space when a voltage is impressed on them. This is exactly what takes place in the Lilienfeld tube and, in fact, the operation of the tube depends on just this conductivity. This article is referred to as showing that applicant in obtaining a higher vacuum has not merely carried forward the work of others, and that his invention is not merely distinguished by a matter of degree, a higher vacuum. When as disclosed the vacuum is pushed beyond .1 of a micron (.0001 m.m.) and the electrodes are freed from gas a new region is entered, and a fundamentally new device is produced. Applied voltage now may be made almost any value without causing positive ionization and the current follows a 3/2 power law which is not true of any of the devices discussed.

The method claims clearly distinguish over the Rollins and Friedrich references by reciting that the impressed voltage is not high enough to produce considerable gas ionization. As the Rollins and Friedrich devices depend upon gas ionization, they necessarily can never enter the region of pressure of interest in this case. Rollins refers to pressures of a millionth of an atmosphere. This is a dense atmosphere for a pure electron discharge, in fact the pressure is a thousand times too great.

Two of the article claims have also been amended. The "structural limitations" in this case are to be found in the differences of vacuum. The difficulty of stating the limits of vacuum in figures is due to the fact that the most deleterious gas is to be found in the metal parts, particularly the anode, and also to the fact the highest permissable pressure varies with the geometric relations of the tube, the size of, and distances between the electrodes. the impressed voltage, and so forth. The electrical characteristics, however. offer a sure and easy test, whether positive gas ionization is present or not. Applicant's new devices are being used daily to carry kilowatts, not microwatts, and with an impressed potential of many thousands of volts exceeding in many cases a hundred thousand volts.

Were these enormous differences in electrical load capacity nothing more than a matter of degree they would be worthy of the most careful consideration as to patentability, as the Courts have held that changes and improvements of degree are not necessarily devoid of patentability, but it is hoped it has been made clear that they involve a fundamental discovery and a fundamentally new device.

An allowance is solicited.

Respectfully submitted,

Albert G. Davis

UNITED STATES PATENT OFFICE
WASHINGTON June 15, 1914.

Mr. Albert G. Davis,
C/o General Electric Co.,
Schenectady, N. Y.

Please find below a communication from the EXAMINER *in charge of the application of*

Irving Langmuir, S. No. 795,610, filed Oct. 16, 1913,
Electrical Discharge Apparatus and the Process of
Preparing the Same.

Thomas Ewing
Commissioner of Patents.

This action is in response to amendment filed May 1, 1914.

Upon reconsideration claims 1 to 5, inclusive, are allowed.

Claims 6 to 9 are rejected as failing to distinguish from the French patent to Lilienfeld, 449,305 of 1913, 250 - 36, (3 sheets, see sheet 1, Figures 1 to 4), which discloses an X-ray tube evacuated to below the pressure at which gas ionization takes place. An auxiliary anode and heated cathode is employed to render the tube conductive to the electrons passing between the main electrodes. The introductory clause "an electrical amplifying device" in claim 9 is insufficient to distinguish from this reference.

Claim 10 is allowable in substance but the word "substantially" or the equivalent thereof should be inserted in line 3 before "independent", and in line 7 "thereby" should be corrected.

Insert F'

The French patent to Lilienfeld # 449,305 of 1913 discloses as the Examiner himself states "an X-ray tube in which an auxiliary anode and heated cathode is employed to render the tube (space) conductive", but it does not follow that this patent discloses a device evacuated below a pressure at which ionization takes place. On the contrary the very fact that the space between the main electrodes is rendered conductive by an auxiliary discharge is clear proof of the fact that gas ionization does occur.

The old type of X-ray tube containing merely two unheated electrodes is self-exciting as the electrons emanating from the cathode collide with gas molecules in their passage to the anode, thereby ionizing these gas molecules. The positive ions in their turn are attracted to the cathode and produce more electrons in their impact upon the cathode surface. The structure disclosed in the Lilienfeld patent is evidently intended to avoid the instability and irregularity of this means for causing ionization by lowering the gas pressure and providing a heated Wehnelt cathode as a source of electrons so as to make the gas ionization positive and controllable. The gas pressure may well be so low that current will not pass between unheated electrodes in the ordinary manner, but the operation of the tube must be dependent upon the presence of gas as otherwise there is no vehicle for the passage of energy through the tube between the main unheated electrodes. This fact is perceived by Dr. Lilienfeld as may be learned from some of his publications. For example, in an article by Dr. Lilienfeld and Dr. Rosenthal in "Fortschritte auf den Gebiet der Röntgenstrahlen" Bd.18,1912, p-256, it is stated, in describing an X-ray tube which is evidently of the same character as the tube described in the French patent, that the device operates by virtue of the presence of positive ions. The authors state that the conductivity momentarily changes with the primary current and that "negative electrons which serve for the transport of current are accompanied by an equivalent number of positive charges." The following language is a translation of a part of the article, which is in the German language.

> "If one now removes to a great degree the matter out of the space by using the best available means for producing a vacuum, excluding ground joints, cements and mercury vapors, it is to be expected that the number of positive charges and therefore also the special density of those charges will become progressively less. And it is to be expected that finally a vacuum will be reached in which the transport of electricity will be entirely carried by negative electrons emitted from the incandescent cathode. As an actual fact the reverse takes place as established above."

In another part of the same article the authors also state that the "current path in a high vacuum traversed by positive and negative charges is evidently a conductor of electricity, and also refer to the fact that the secondary cathode sends out "cathode rays which appear to be liberated from its surface by bombardment with the carriers of positive charges upon its surface in the extremely high vacuum." This article refers to certain prior publications which also set forth this same theory with reference to certain experimental devices other than X-ray tubes. In a later article in this same publication, Volume 22, 1913, there may be found another paper by Dr. Rosenthal on the Lilienfeld Roentgen tube in which the author explains the operation of the tube, assuming that positive ionization occurs. In the interest of brevity only a few statements will be quoted from this paper.

> "For the non-physicist, the operation of the tube may perhaps be theoretically explained as follows: By means of the conductivity-discharge, proceeding from the incandescent electrode, positively as well as negatively charged particles are produced in the chamber of the tube which originally is impermeable to the Roentgen discharge. The positive particles are attracted by the negatively charged concave surface of the Roentgen cathode, rebound upon it, and thereby give the impulse which is necessary for the release of the bundle thrown upon the anti-cathode, and there create the Roentgen rays. As the conductivity current increases, there will be more positive particles in the tube, it will be easier for the cathode surface to produce a sufficient number of them -- consequently the voltage at the surface of the cathode will be smaller, the cathode ray here released will be slower, and the Roentgen ray will be weaker -- and conversely."

Some of the language of the various articles indicates that the author attempted to harmonize his theory of the independence of the tube from the degree of vacuum and his views as to the role of positive ions by assuming a "positive ion" produced in some way independently of gas. In this view, if it is indeed to be ascribed to him, he is alone in the scientific world. However, the claims do not depend on any such theory for their patentability. The "evidences of positive ionization" are observable, well-known phenomena, no matter what we may think about the origin of the positive ion.

The present applicant has found that the gas contained in the electrodes, particularly the anode, is much more subject to ionization and for the operation of a tube operating by pure electron discharge gas in the electrodes is more deleterious than gas residues in the evacuated space. The specification sets forth at length how this ionizable gas may be removed from the anode. That the electrodes in this tube contain gas is indicated by the following statement in the Rosenthal article. "In case of overload gas is somewhat given off by the electrodes so that the tube temporarily loses its hardness."

The article claims are limited not merely by a statement that the highest obtainable vacuum is produced as after all the highest degree of vacuum obtainable varies with the character of the means used for producing the vacuum. The article claims are limited by reference to the electrical characteristics of the present device or by statements to the effect that positive ionization is absent during the operation of the device. The specification contains descriptive matter as to what is meant by positive ionization so that this term is a short statement of a collection of phenomena which are now recognized by scientists as indicating gas ionization. A recent book on X-rays by G. W. C. Kaye (Longmans, Green & Co.) is respectfully called to the Examiner's attention as giving in a clear, readable form some information regarding this type of device which while otherwise available is more or less scattered through the literature.

At a personal interview with the Examiner it was suggested that the description of the electrical characteristics of the device be somewhat amplified. This has been done.

Reconsideration of the claims as amended and favorable consideration of certain new claims added to more completely protect the invention is respectfully solicited.

Respectfully submitted,

Albert G. Davis

Attorney for Langmuir.

DEPARTMENT OF THE INTERIOR

UNITED STATES PATENT OFFICE

WASHINGTON Jan. 12, 1915.

Mr. A. G. Davis,
C/o General Electric Co.,
Schenectady, N. Y.

Please find below a communication from the **EXAMINER** *in charge of this application of*

I. Langmuir, S. No. 795,610, filed Oct. 16, 1913, Electrical Discharge Apparatus and the Process of Preparing the Same.

Thomas Ewing
Commissioner of Patents.

This action is in response to amendment filed Dec. 19, 1914.

Claim 10, line 7, the word "thereby" is misspelled.

Upon careful reconsideration all the claims in this case are deemed allowable with the exception of claim 12. This claim does not distinguish from the French patent 449,306, for example, which shows an evacuated envelope, a cathode adapted to be heated to incandescence and an anode. It is a well settled rule that a claim must distinguish from a reference in some way other than by a mere statement of function. It is suggested, therefore, that claim 12 be amended by inserting after the comma in line 4 the words said envelope being evacuated to such a degree that.

The case is otherwise in condition for immediate allowance.

Wm A Kinnan
Examiner, Division XVI.

DEPARTMENT OF THE INTERIOR
UNITED STATES PATENT OFFICE

WASHINGTON Feb. 19 1915.

IN REMITTING THE FINAL FEE GIVE THE SERIAL NUMBER AT THE HEAD OF THIS NOTICE

Irving Langmuir, Assor.

Sir: Your APPLICATION for a patent for an IMPROVEMENT in Electrical Discharge Apparatus and the Process of Preparing the Same,
filed Oct. 16, 1913, has been examined and ALLOWED.

The final fee, TWENTY DOLLARS, must be paid not later than SIX MONTHS from the date of this present notice of allowance. If the final fee be not paid within that period, the patent on this application will be withheld, unless renewed with an additional fee of $15, under the provisions of Section 4897, Revised Statutes.

The office delivers patents upon the day of their date, and on which their term begins to run. The printing, photolithographing, and engrossing of the several patent parts, preparatory to final signing and sealing, will require about four weeks, and such work will not be undertaken until after payment of the necessary fee.

When you send the final fee you will also send, DISTINCTLY AND PLAINLY WRITTEN, the name of the INVENTOR, TITLE OF INVENTION, AND SERIAL NUMBER AS ABOVE GIVEN, DATE OF ALLOWANCE (which is the date of this circular), DATE OF FILING, and, if assigned, the NAMES OF THE ASSIGNEES.

If you desire to have the patent issue to ASSIGNEES, an assignment containing a REQUEST to that effect, together with the FEE for recording the same, must be filed in this office on or before the date of payment of final fee.

After issue of the patent uncertified copies of the drawings and specifications may be purchased at the price of FIVE CENTS EACH. The money should accompany the order. Postage stamps will not be received.

Final fees will NOT be received from other than the applicant, his assignee or attorney, or a party in interest as shown by the records of the Patent Office.

Respectfully,

Thomas Ewing
Commissioner of Patents.

UNCERTIFIED CHECKS WILL NOT BE ACCEPTED.

AFFIDAVIT

City of Washington, :
: ss:-
District of Columbia, :

IRVING LANGMUIR, of Schenectady, County of Schenectady, State of New York, being duly sworn, deposes and says that he is the same Irving Langmuir who filed the above-identified application for Letters Patent.

That he has read and is familiar with the description of experiments in J. J. Thomson's "Conduction of Electricity Through Gases", 1906 Edition, pp. 192 to 193, involving a hot cathode device;

That he has personally made numerous experiments involving the conduction of electricity through a rarified gas both below and above the pressure of .001 m.m. which is given as the lowest possible pressure attainable in the experiments described in the above article;

That he knows from his general familiarity with the development of vacuum pumps and methods of producing high vacua that up to the year 1906, the date of publication of the above book, the only air pumps available for producing high vacua were mercury pumps. Since no statement is made by J. J. Thomson of special precautions to remove mercury vapor, and since it was not customary at that time to use means for excluding mercury vapor, it is to be pre-

2

sumed that mercury vapor was present in the evacuated tube. That as far as he is aware the only apparatus for measuring pressures as low as .001 m.m. known at the time of publication of J. J. Thomson's book was the McLeod gauge which does not indicate the presence of condensable vapors, such as mercury vapor or water vapor.

That from his own observation based on numerous experiments, he knows that in an incandescent cathode device of the type described by J. J. Thomson in which the residual gas pressure is as high as .001 m.m. the current will not vary with the 3/2 power of the applied voltage, even if the residual gases are non-condensable gases such as could be indicated by a McLeod gauge. In the presence of mercury vapor or water vapor, the deviation of the current-voltage relation from the 3/2 power law will be even more marked.

ELECTRICAL DISCHARGE APPARATUS
AND THE PROCESS OF PREPARING
THE SAME

L

AMENDMENT UNDER RULE 78

Honorable Commissioner of Patents,

Sir:

H

Please amend the above application as follows without withdrawing the same from issue.

Page 5, line 10, after the sentence ending with "volts" insert:

H

Par L
Lang 829

- J. J. Thomson in the 1906 edition of his book "Conduction of Electricity Through Gases" describes on pages 192 and 193 an apparatus comprising an incandescent cathode and an anode located in a glass vessel evacuated to a pressure of .001 m.m. of mercury. This pressure is too high to enable a pure electron discharge to occur, particularly in the presence of mercury vapor which was inevitably present. In devices made in accordance with my invention the residual gas is reduced to a materially lower pressure. -

Page 4, after the sentence ending with "operable" insert: Devices made and operated in accordance with my invention are capable of transmitting currents materially exceeding one-tenth of a milliampere without causing positive ionization to take any essential part in the operation of the device, though the voltage is materially above the ionizing voltage.

H²

N

Cancel claim 14 and substitute the following claim:

H³

14. An electrical device comprising a gas-tight envelope, electrodes therein, means for producing an emission of electrons from one of said electrodes, independently of the operating voltage, said device being

~~evacuated to a pressure materially below about .001 millimeter of mercury pressure, the residual gas pressure being so low that conduction of electricity can occur therein operatively independent of positive ionization with currents and voltages which would with other conditions be great enough to cause appreciable positive gas ionization.~~

Add the following claim:-

~~28. An electrical device comprising an evacuated gas-tight envelope, electrodes therein, means for producing an emission of electrons from one of said electrodes, independently of the operating voltage, the pressure of residual gas in said device being so low that conduction of electricity therethrough occurs operatively independent of positive gas ionization with currents materially greater than one-tenth of a milliampere.~~

Remarks

This amendment is made to distinguish claim 14 over a description on pages 192 and 193 of J. J. Thomson's book "Conduction of Electricity Through Gases", 1906 Edition. This publication was not cited during the prosecution of the case but was called to the attention of applicant's attorney after the application was allowed. At a personal interview with the Primary Examiner at which Dr. Langmuir, the inventor, was present, the work of Richardson and J. J. Thomson in the field of incandescent cathode devices was discussed and claims such as submitted herewith were indicated as suitable by the Examiner to distinguish over the Thomson reference.

As pointed out by Dr. Langmuir at the interview and in the accompanying affidavit, the device described by J. J. Thomson could not have operated at a gaseous pressure of .001 m.m. of mercury (the lowest possible with the air-pump employed) without positive ionization as would be indicated by a deviation from the 3/2 power law of current-voltage relation. In a device in which gas ionization is not absent the current will increase with the electromotive force, (but not by the 3/2 power ratio) and then reach a saturation value as described by Thomson, but the fact that a saturation value is obtainable does not prove that gas ionization is absent.

An affidavit by Dr. Langmuir is hereby submitted in accordance with the Examiner's suggestion to set forth the facts brought out in the interview. Attention is particularly directed to the fact that so far as may be inferred from the information given by Thomson and the general knowledge of the art, mercury vapor must have been present in the Thomson device. Hydrogen gas will permit higher residual gas pressures without vitiating an electron discharge by positive ionization but even in the case of hydrogen, pressures as high as .001 m.m. of mercury are too high to avoid positive ionization when using voltages and currents high enough to cause appreciable positive ionization.

The current values given by Thomson on page 194 are extremely minute, 1000×10^{-9} to 1290×10^{-8} amperes. (one to 12.9 millionths of an ampere) With these minute currents the more easily recognizable evidences of positive gas ionization such as blue glow, glass fluorescence and disintegration of the cathode are practically absent and J. J. Thomson not being aware of any such delicate test as the 3/2 power current-voltage law could not be expected to be aware that the operation of his device was accompanied by gas ionization.

A new claim is also submitted by this amendment distinguishing over the Thomson reference by reciting that the device is capable of transmitting current values materially greater than one-tenth of a milliampere. The values quoted by Thomson from Richardson's work are of a lower order of magnitude, and as explained above it was only by virtue of the minuteness of the current values that Thomson failed to observe evidences of positive ionization.

It is believed that from the understanding of the situation brought out at the interview this amendment will be found proper to clearly distinguish over the J. J. Thomson reference which after all describes nothing more than a mere laboratory experiment which left the subject clouded in mystery and which never led to any industrially useful devices. In 1904 the year following the publication of the Richardson article to which J. J. Thomson refers (foot-note page 194), Wilson in Phil. Trans. p. 243, makes the statement that:

> "It is probable that a pure platinum wire heated in a perfect vacuum would not discharge any electricity at all, either positive or negative, to an extent appreciable on a galvanometer."

Pring and Parker in 1912 (Phil. Mag. 23,192) conclude that Richardson's results must have been erroneous. Other illustrations might be given of the confusion of theory and observation.

Since the work of Langmuir and Coolidge no doubt exists that a pure electron discharge is a reality. Even Sir. J. J. Thomson in a recent address (See the J. of the Inst. of Metals, 1915, Vol. XIV) uses the Coolidge tube as an illustration to show that the presence of gas is not absolutely essential for the emission of electrons.

Respectfully submitted,

Albert G. Davis

Attorney for Langmuir.

I. Langmuir, S. No. 84,242, filed Mar. 14, 1916, Electrical Discharge Apparatus and the Process of Preparing the Same, renewal of 795,610, filed Oct. 16, 1913.

Thomas Ewing
Commissioner of Patents.

The following claims are suggested to applicant for purposes of interference and if presented the application will be withdrawn from issue. Applicant is given twenty days from date of this letter within which to present them. Failure to present such claims within the time stated will be held an abandonment of their subject-matter.

In a thermionic device, a vacuum tube, a heated electron-emitting cathode and an anode enclosed in said tube, a circuit outside of said tube connecting said cathode and anode, and a source of direct current included in said circuit, the vacuum in said tube being so high that no sudden increase in current due to gas ionization is possible except at voltages higher than that required to produce the saturation current at the operating temperature of the cathode.

In a thermionic device, a vacuum tube, a heated electron-emitting cathode and an anode enclosed in said tube, a circuit outside of said tube connecting said cathode and anode, and a source of direct current included in said circuit, the vacuum in said tube being so high that a working margin of safety exists between the voltage at which all electrons capable of being emitted by the filament at the temperature at which the latter is maintained flow to the plate and the voltage at which there is appreciable ionization of the residual gas of said tube.

A vacuum tube device of the thermionic type, having the area of the filament and the degree of vacuity so related to the temperature and the impressed voltage at which the tube is to be worked, that no appreciable ionization takes place when substantially all the electrons emitted are drawn to the anode.

A thermionic device wherein an electron discharge takes place between a heated cathode and an anode in a vacuum, the degree of said vacuum being so coordinated with the volume and velocity of said discharge that no gas ionization can occur during normal operation.

The case, above referred to, is adjudged to interfere with others, hereafter specified, and the question of priority will be determined in conformity with the Rules.

The statement demanded by Rule 110 must be sealed up and filed on or before SEP 5 1916 *, with the subject of the invention, and name of party filing it, indorsed on the envelope. The subject-matter involved in the interference is*

1. In a thermionic device, a vacuum tube, a heated electron-emitting cathode and an anode enclosed in said tube, a circuit outside of said tube connecting said cathode and anode, and a source of direct current included in said circuit, the vacuum in said tube being so high that no sudden increase in current due to gas ionization is possible except at voltages higher than that required to produce the saturation current at the operating temperature of the cathode.

2. In a thermionic device, a vacuum tube, a heated electron-emitting cathode and an anode enclosed in said tube, a circuit outside of said tube connecting said cathode and anode, and a source of direct current included in said circuit, the vacuum in said tube being so high that a working margin of safety exists between the voltage at which all electrons capable of being emitted by thefilament at the temperature at which the latter is maintained flow to the plate and the voltage at which there is appreciable ionization of the residual gas of said tube.

3. A vacuum tube device of the thermionic type, having the area ofthe filament and the degree of vacuity so related to the temperature and the impressed voltage at which the tube is to be worked

that no appreciable ionization takes place when substantially all the electrons emitted are drawn to the anode.

4. An electrical discharge device comprising a gas-tight envelope, an incandescent cathode, and a gas-free anode, the space in said envelope being evacuated to below the pressure at which deleterious gas ionization takes place, the current passed by said device over a working range of voltage and temperature varying with the 3/2 power of the impressed voltage for voltages above a minimum voltage depending on the temperature of the cathode.

5. A high vacuum electron discharge device comprising an envelope, an incandescent cathode, and an anode, the space in said envelope being evacuated to such degree that the passage of current produces no appreciable positive ionization when the impressed voltage is as high as 200 volts.

6. An electrical discharge device comprising a gas-tight evacuated envelope, a cathode adapted to be heated to incandescence, an anode, the space in said envelope being evacuated to such a degree that the current flowing between said electrodes varies with the 3/2 power of the impressed voltage over a working range of current values exceeding about five milliamperes.

7. An electrical discharge device comprising a gas-tight envelope, an incandescent cathode, an anode, and means for independently heating the cathode, the parts of said apparatus and the enclosed space being deprived of gas to such extent that the device is operable with currents varying with the 3/2 power of the voltage over a range of impressed voltages determined by the cathode temperature, the current at voltages above this range being substantially constant.

The interference involves your application above identified and

An application for Thermionic Devices and Method of Constructing and Operating the Same, filed by Harold DeForest Arnold, 140 South Munn Avenue, East Orange, N. J., whose attorneys are DeWitt C. Tanner and John G. Roberts, 463 West St., New York, N. Y., and whose assignee is the Western Electric Co., of New York, N. Y.

IN THE UNITED STATES PATENT OFFICE.

In re Application of
Irving Langmuir,
Serial No. 84,242,
Filed March 14, 1916,
Div. 16, Room 109.

ELECTRICAL DISCHARGE APPARATUS AND THE PROCESS OF PREPARING THE SAME.

Hon. Commissioner of Patents,

Sir:-

It is respectfully requested that this application be referred to the Primary Examiner for consideration and admission of the following amendments to the specification and claims.

As suggested in the brief filed by Langmuir in connection with the motion by the party Arnold in Interference 40,380 invoking the supervisory authority of the Commissioner to secure an order to take testimony in respect to certain references, the proposed claims are submitted as descriptive in the opinion of the party Langmuir of novel features of the present invention over the references cited; it is requested, if found desirable in the progress of the interference proceedings, that some or all of these claims be proposed by the Patent Office to the party Arnold as prospective counts of the issue:

✓ Page 2, line 27, after the sentence ending with "cathode" insert:

~~- As determined by Frank and Hertz (Ber. d. Deut. Phys. Ges. Vol. 15, 34, 1913) and by earlier investigators referred to by Frank and Hertz, the ionization of gases at low pressures by collision~~

K'

Pen

~~with electrons occurs at definitely determinable voltages, these voltages being known as the ionization voltages. The ionization voltage values found by Frank and Hertz are as follows: for helium 20.5 volts, neon 16 volts, argon 12 volts, hydrogen 11 volts, oxygen 9 volts and nitrogen 7.5 volts. -~~

✓✓ Page 3, line 27, after the paragraph inserted by amendment of Dec. 17, 1914, add the following:

~~- In a device in which the conduction of current is purely electronic, and the effect of positive ions is negligible, the conduction of current is governed, over a certain range, on the one hand by the effect of the impressed voltage (which tends to propel the electrons across the vacuous space), and on the other hand by the mutual repulsion of the electrons in the space, which tends to limit or inhibit the current. This last mentioned phenomenon, the current limiting effect of the electric field of the electrons on each other, termed the "space charge effect", is discussed and analysed by me in a paper read before the Physical Society on October 18, 1913, which was abstracted in the Physical Review for November 1913, and published in full in the Physical Review for December 1913 and again published in somewhat modified form in the Physikalische Zeitschrift for January and March 1914.~~

Perrin

K^2

The geometric proportions of the device also affect the amount of current which will pass with a given voltage, but as these conditions remain fixed for a given device they may be represented by a constant in an equation expressing the relation between the current and the voltage.

As already stated above, the current (I) will vary in the particular device described herein, with the 3/2 power of the voltage (V), the equation thus being:

$I = aV^{3/2}$ (a being [illegible] constant).

As is well known, if we produce a logarithmic graph of any equation in which one variable of the equation varies as a power of the other variable, as for example, an equation of the general form $y = x^n$, (as by plotting logarithms of x as abscissae and logarithms of y as ordinates) we find that this graph is a straight line.

Hence, the relation between current and voltage in a device operating by pure electronic conduction independent of gas ionisation may be expressed by the statement that when with a sufficient electron emission the logarithms of the current values transmitted between cathode and anode are plotted as ordinates against the logarithms of the respective voltages impressed between cathode and anode as abscissae, the slope of the line obtained does not increase for increasing voltage values over a working range of voltages.

As above indicated, one of the first indications of positive ionization may be observed by erratic readings in measuring devices connected in circuit with an electron discharge device under observation. These erratic readings, of course, will produce a sudden change or discontinuity in the logarithmic graph plotted as above described, and any such irregularities will be more manifest when observed as deviations from a straight line than when the readings are plotted directly.

In a device in which positive ionization occurs, the exponent of the impressed voltage (V) will not be a constant but will increase as the voltage increases and consequently also as the amount of ionization increases.

As shown in the paper in the Physical Review, December 1913, positive ionization causes with a progressive increase of voltage a progressive increase of the exponent of V in the equation $I = aV^{3/2}$, and hence the slope of the logarithmic plot increases when positive gas ionization occurs.

~~ert C2~~

Add the following claims;

81-84. A thermionic device comprising a vacuum tube, a heated electron emitting cathode and an anode enclosed within said tube, the parts of said tube and the space therein being deprived of gas to such an extent that

C3

Pen

over a working range of voltages exceeding the ionization voltage characteristic of whatever residual gas remains within the tube, a current through the evacuated space is operatively independent of positive gas ionization.

34 ~~25~~. A thermionic device comprising a vacuum tube, a cathode and an anode contained therein, and means for heating said cathode to incandescence, the parts of said tube and the space therein being deprived of gas to such an extent that, with the cathode at a sufficiently high temperature, a current may be passed through the evacuated space with a range of impressed voltages exceeding about 30 volts which is unaccompanied by such indications of positive ionization as a sudden change of current or blue glow.

9

20 ~~26~~. An electrical device comprising the combination of a sealed evacuated envelope, a cathode adapted to be independently heated, and an anode within said envelope, an external circuit connected to said electrodes, and a source of electromotive force applied to said circuit, the degree of vacuity and the electron emission of the cathode being so related to the potential of said source that the flow of current over a range of voltage materially above the ionization voltage is governed by the electric field of the electrons in the vacuous space and the potential applied to said electrodes, operatively independent

R3

of gas ionization. M'fallons

Per n

~~36. A thermionic device comprising a vacuum tube, a cathode and an anode contained therein, and means for heating said cathode to incandescence, the parts of said tube and the space therein being deprived of gas to such extent that, with the cathode at a sufficiently high temperature, the slope of the line obtained by plotting the logarithms of currents transmitted thru the vacuous space as ordinates against the logarithms of voltages impressed upon said electrodes as abscissae does not increase for increasing voltage values over a working range of voltages exceeding the ionization voltage.~~

~~37. A thermionic device comprising a vacuum tube, a cathode and an anode contained therein, and means for heating said cathode to incandescence, the parts of said tube and the space therein being deprived of gas to such extent that with the cathode at a sufficiently high temperature the line obtained by plotting the logarithms of currents transmitted thru the vacuous space as ordinates against the logarithms of impressed voltages as abscissae is a straight line for voltage values over a working range of voltages exceeding the ionization voltage, and there is no sudden change nor discontinuity in the line.-~~

ELECTRICAL DISCHARGE APPARATUS, PROCESS OF PREPARING ETC.

SUPPLEMENTAL PROPOSED AMENDMENT.

Honorable Commissioner of Patents,

S i r:-

C

On or about January 29, 1917, an amendment to this application was proposed containing certain claims and certain proposed changes or additions to the specification. Under date of February 23, 1917, the Honorable Acting Commissioner of Patents, to whom the amendment was submitted in the course of proceedings in the interference, Arnold vs. Langmuir, No. 40,380, in which this case is involved, held as follows:

> "Langmuir has filed an amendment to his application containing certain claims and requests that they be added to the issue of the interference. Under the circumstances this amendment may be considered by the Law Examiner in connection with the motion to dissolve."

The following is a proposed amendment supplemental to the prior proposed amendment above referred to.

✓ ✓ Cancel the insertion directed to be entered on page 3, line 10 of the specification, after the sentence ending with the word "volts", this insertion being contained in an amendatory paper dated April 29,1916.

✓ Page 3, line 22, following the insertion after the word "voltages" directed by the amendment dated December 17, 1914, add the following:

5

- This current is termed the saturation current, and the region in which the current is substantially independent of the voltage or closely approaches thereto may be termed the saturation region or more briefly designated merely as saturation. -

L¹

u n

✓ Page 3, line 27, following the long insertion directed to be added at that point by the amendment of January 29, 1917, add the following:

- The effect of ionization is especially marked in that region of operation where the current is limited by the space charge effect already discussed, and changes in curvature of the discharge characteristic may occur as indicated unaccompanied by any visible evidence of ionization such as blue glow or the like. At saturation on the other hand, the discharge is much less sensitive, and in fact the discharge may actually exhibit marked blue glow effects along with a flat or straight saturation curve. -

u

n

L²

✓ Please add the following claims, the same being numbered from 1 to 9 inclusive.

4 1. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the governing or limiting action on the space current due to the electric field of said electrons is substantially unaffected by positive ionization and by secondary electron emission from the

L³

walls of the tube.

2. A discharge tube having a cathode adapted to emit electrons and an anode adapted to receive said emitted electrons, the tube walls being fashioned or shaped [illegible] permit the direct passage of a useful proportion of said electrons from cathode to anode, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the space current is governed or limited by the electric field of said electrons substantially unaffected by positive ionization.

3. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that in that range the space current is governed by the combined effect of the electric field of said electrons and the potentials applied to said electrodes, the governing or limiting of the current being substantially unaffected by positive ionization and by secondary electron emission from the walls of the tube.

4. A discharge device comprising a tube and electrodes therein one of which is adapted to emit electrons, the degree of evacuation and the relation of the parts of the device being such that the device is capable of being so operated, when voltages materially higher than ionization voltages are impressed upon electrodes of the device and when the electron emission has any value such that the space current is below the

saturation region at such voltages, that the slope of the line obtained by plotting the logarithms of values of said current as ordinates against the logarithms of the corresponding values of said impressed voltages as abscissae shows no increase for increasing voltage values.

12.8

5. A discharge device comprising a tube and electrodes therein one of which is adapted to emit electrons, the degree of evacuation and the relation of the parts of the device being such that the device is capable of being so operated, when voltages materially higher than ionization voltages are impressed on electrodes of the device and when the electron emission has any value such that the space current is below the saturation region at such voltages, that the line obtained by plotting the logarithms of any values of said current below the saturation region as ordinates against the logarithms of the corresponding values of said impressed voltages as abscissae, is straight and continuous.

6. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated, when voltages materially higher than ionization voltages are impressed on electrodes of the tube and when the electron emission has any value such that the space current is below the saturation region at such voltages, that said current varies as the three halves power of said impressed voltages.

7. A discharge device comprising a tube and

electrodes therein one of which is an electron emitting cathode, the degree of evacuation of said device and the relation of the parts of the device being such that the device is capable of being so operated, when voltages materially higher than ionization voltages are impressed on ~~electrons~~ electrodes of the device and when the electron emission is such that the space current is below the saturation region at such voltages, that said current is substantially independent of the cathode temperature and unaffected by secondary electron emission from the walls of the tube.

~~electrodes See Langmuir [illegible] page 5 #1~~

8. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the space current is governed or limited by the combined effect of the electric field of said electrons and the potentials applied to said electrodes, substantially unaffected by positive ionization, the heating effect in the tube due to said current occurring substantially only at one or more of said electrodes.

9. A discharge tube having a cathode adapted to emit electrons, an anode adapted to receive electrons and tube walls fashioned or shaped so as to permit the free passage of a useful proportion of said electrons from cathode to anode, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of operation with

stable and reproducible results substantially unaffected by positive ionization, with currents of at least 5 milliamperes and with voltages of at least 200 volts.

WASHINGTON

U. S. PATENT OFFICE
APR 5 1921
MAILED

Mr. Albert G. Davis,
General Electric Co.,
Schenectady, N. Y.

Please find below a communication from the EXAMINER in charge of the application of

Irving Langmuir, Ser. #84,242, filed Mar. 14, 1916;
renewal of Ser. #795,670, filed Oct. 16, 1913.

Electrical Discharge Apparatus and the Process of Preparing same.

M. H. COULSTON
Commissioner of Patents.

The following counts have been added to interference No. 40,380, ARNOLD vs. LANGMUIR in accordance with the decisions of the Law Examiner dated Feb. 25, 1921 and March 18, 1921:

2. An electrical device comprising the combination of a sealed evacuated envelope, a cathode adapted to be independently heated, and an anode within said envelope, an external circuit connected to said electrodes, and a source of electromotive force applied to said circuit, the degree of vacuity and the electron emission of the cathode being so related to the potential of said source that the flow of current over a range of voltage materially above the ionization voltage is governed by the electric field of the electrons in the vacuous space and the potential applied to said electrodes, operatively independent of gas ionization.

3. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the governing or limiting action on the space current due to the electric field of said electrons is substantially unaffected by positive ionization and by secondary electron emission from the walls of the tube.

4. A discharge tube having a cathode adapted to emit electrons and an anode adapted to receive said emitted electrons, the tube walls being fashioned or shaped to permit the direct passage of a useful proportion of said electrons from cathode to anode, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the space current is governed or limited by the electric field of said electrons substantially unaffected by positive ionization.

5. A discharge tube having electrodes at least one of
which is adapted to emit electrons, the gas content or resi-
due of said tube and the relation of the parts of the tube
being such that the tube is capable of being so operated in
a range below saturation and materially above ionization vol-
tages that in that range the space current is governed by the
combined effect of the electric field of said electrons and
the potentials applied to said electrodes, the governing or 3
limiting of the current being substantially unaffected by
positive ionization and by secondary electron emission from
the walls of the tube.

6. A discharge device comprising a tube and electrodes
therein one of which is adapted to emit electrons, the degree
of evacuation and the relation of the parts of the device
being such that the device is capable of being so operated, 4
when voltages materially higher than ionization voltages are
impressed upon electrodes of the device and when the electron
emission has any value such that the space current is below
the saturation region at such voltages, that the slope of the
line obtained by plotting the logarithms of values of said
current, as ordinates against the logarithms of the corres- 4
ponding values of said impressed voltages as abscissae shows
no increase for increasing voltage values.

7. A discharge device comprising a tube and electrodes
therein one of which is adapted to emit electrons, the degree
of evacuation and the relation of the parts of the device
being such that the device is capable of being so operated,
when voltages materially higher than ionization voltages are
impressed on electrodes of the device and when the electron 5
emission has any value such that the space current is below
the saturation region at such voltages, that the line obtained
by plotting the logarithms of any values of said current below
the saturation region as ordinates against the logarithms of
the corresponding values of said impressed voltages as abscissae
is straight and continuous.

8. A discharge tube having electrodes at least one of
which is adapted to emit electrons, the gas content or residue
of said tube and the relation of the parts of the tube being
such that the tube is capable of being so operated, when vol-
tages materially higher than ionization voltages are impressed 6
on electrodes of the tube and when the electron emission has
any value such that the space current is below the saturation
region at such voltages, that said current varies as the three
halves power of said impressed voltages.

9. A discharge device comprising a tube and electrodes
therein one of which is an electron emitting cathode, the de-
gree of evacuation of said device and the relation of the parts
of the device being such that the device is capable of being so
operated, when voltages materially higher than ionization vol- 7
tages are impressed on electrodes of the device and when the
electron emission is such that the space current is below the
saturation region at such voltages, that said current is sub-
stantially independent of the cathode temperature and unaffected
by secondary electron emission from the walls of the tube.

Ser. #84,242 - #3.

10. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the space current is governed or limited by the combined effect of the electric field of said electrons and the potentials applied to said electrodes, substantially unaffected by positive ionization, the heating effect in the tube due to said current occurring substantially only at one or more of said electrodes. 8

11. A discharge tube having a cathode adapted to emit electrons, an anode adapted to receive electrons and tube walls fashioned or shaped so as to permit the free passage of a useful proportion of said electrons from cathode to anode, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of operation with stable and reproducible results substantially unaffected by positive ionization, with currents of at least 5 milliamperes and with voltages of at least 200 volts. 9

12. Apparatus for controlling an electric current comprising a vacuum tube, an anode and an electron emitting cathode in the circuit of said current and within said tube, the degree of evacuation of the tube and the relation of its parts being such that for voltages materially above ionization voltage the current is governed or limited by the electric field of the electrons in said tube substantially unaffected by positive ionization, and a third electrode in said tube by which an auxiliary controlling electromotive force may be superposed to modify the effect of said electric field and control said current in a stable and reproducible manner.

13. The method of controlling an electric current in one circuit by an electromotive force in another circuit which consists in causing said current at voltages materially above ionization voltages to pass as a discharge across a vacuous space between an electron emitting cathode and an anode, maintaining a high vacuum in said space, governing or limiting the current by a space charge effect in said space substantially unaffected by positive ionization, and superimposing the effect of said electromotive force on said space charge effect to control said current in a stable and reproducible manner.

The preliminary statement required by Rule 110, as to the added counts only, should be filed on or before MAY 2 1921

The relation of all the counts to the claims of the parties is now as follows:

Counts:	Arnold:	Langmuir:
1	17	14
2	20	35
3	21	1
4	22	2
5	23	3
6	24	4
7	25	5

Ser. #84,242 - #4.

Counts:	Arnold:	Langmuir: (con
8	26	6
9	27	7
10	28	8
11	29	9
12	30	38
13	31	39

In applicant's claim 7, line 7, "electrons" should be changed to electrodes to agree with count 9 as declared.

Serial No. 84,242, :
Filed (Renewed) March 14, 1916, :
Division 51. Room 240 :

ELECTRICAL DISCHARGE APPARATUS AND THE PROCESS OF PREPARING THE SAME.

SEP [illegible] 1925
DIV 51 FILED

n

Honorable Commissioner of Patents,

S i r:-

Please amend the above-entitled application as follows:

Page 1:

Line 6, after "PREPARING" insert -AND USING-

Line 13, cancel "having" and substitute - which make possible -

Line 15, change "operable" to - operation -

Line 16, after "voltages" insert - but the invention is also applicable and useful for moderate loads and moderate voltages -

n'

Line 31, cancel "an ordinary" and substitute - a Roentgen -

Page 2:

Cancel lines 2 to 22 inclusive, and the first eight words in line 23, and substitute:

n^2

- The passage of an electric current across a tube ordinarily involves the movement of negative charges called electrons which, under the influence of the impressed voltage, pass from the cathode to the anode through the vacuous space. If these electrons when moving above a certain velocity collide with gas molecules they tend to ionize the molecules, splitting them up into electrons and larger and more slowly moving ions. Under these circumstances the phenomena of conduction across the tube are the result of the action and interaction of the electrons and the ions; these phenomena are in general erratic and non-reproducible.

Line 24, cancel "electrically"

Line 25, before "is" insert - ~~it~~ -

n3

Line 25, before "The" insert - ~~as~~ As gas ionization continues at higher voltages a blue glow may appear.

Line 27, after "cathode." cancel the matter inserted by amendment of January 29, 1917, and substitute: - The ionization of gases at low pressures by collision with electrons occurs at definitely determinable voltages, these voltages being known as the ionization voltages. These voltages are different for different gases. In the case of gases such as nitrogen, hydrogen, oxygen, argon, helium and neon, they are of the order of magnitude of fifteen to twenty-five volts.

n4

Line 30, after "device" insert - with three electrodes -

Page 3:

Line 5, before "somewhere" insert - to be important -

Line 6, after "volts" insert:

n 5

Copied

- Another discharge device previously used to some extent was the Fleming Valve. This was a two-electrode tube which, so far as I am aware, was always used at voltages well below the voltages at which positive ionization by collision occurs. It was

N5

not evacuated in such a manner as to permit it to be used at voltages materially above these ionization voltages without manifesting substantial positive ionization effects.

Line 10, after "volts" change the period to a semi-colon and insert - indeed no prior discharge devices are known to me operating in a practically usable manner and without substantial positive ionization effects with currents as great as about one-tenth of a milliampere with voltages as high as about forty volts.

n6

Lines 15 and 16, mark so that there will be no new paragraph at this point.

Line 17, after "blue glow" insert - , glass fluoresence-; after "all" insert - readily -

Line 18, after "are" insert - ordinarily -

Cancel everything between the period in line 18 and the period in line 24, and insert:-

n7

In most devices of simple construction which embody my invention, the discharge current passing through a given space with the cathode at a sufficiently high temperature with respect to the voltages employed, varies directly with the 3/2 power of the impressed voltages. This 3/2 power law can be readily derived mathematically for a tube in which there is substantially no positive ionization on the assumption that the whole surface of the cathode is at a uniform potential, that the electrons escape from the cathode with negligible velocities and that the walls of the tube do not carry appreciable electric charges.

In most simple devices embodying my invention, these conditions are so well fulfilled that the current does vary in proportion to the 3/2 power of the voltage over wide ranges of voltage above the ionizing voltages. This means that if the logarithm of the current is plotted against the logarithm of the voltage, the resulting plot is a straight line whose slope is 3/2. Or, in many cases it is more convenient to make use of the equivalent relation, that the 2/3 power of the current plotted as ordinates against the anode voltages as abscissae gives a straight line.

In devices in which there is substantial positive ionization, on the other hand, even when the pressures of gas are so low that only very small currents could be carried by positive ions, the currents begin to increase with voltage more rapidly than according to the 3/2 power law as soon as the anode voltage materially exceeds the ionizing potential of the gas.

In devices embodying my invention which have more than two electrodes, or with special constructions, as where the cathode is a filament, so long that it cannot be considered an equi-potential surface, the 3/2 power law may be more or less masked. However, the effects thus introduced will be readily understood by those skilled in the art, and appropriate methods of identifying the pure electron discharge can easily be found corresponding to the special construction. For example, when such tubes have more than two electrodes and the temperature of the cathode is sufficiently high with respect to the voltages employed, the discharge will usually be characterized by a linear relation between the 2/3 power of the total electron current from the cathode and the voltage applied to any other electrode, the remaining electrodes being kept at constant potential. Another test that can often be made with a three electrode tube is to connect the grid directly to the anode, or to the negative end of the cathode, and observe whether the current varies as the 3/2 power of the voltage.

If for a given cathode temperature the voltage is sufficiently high to cause all of the electrons emitted or liberated at the cathode to be drawn away, then a further increase in voltage produces substantially no change in the current. The current thus determined is called the saturation current, and the range of operation in which the current is substantially independent of the voltage or approaches this condition may be called the saturation range or more briefly designated merely as saturation. If for a given cathode temperature the voltage is not high enough to cause all of the electrons which are emitted or liberated at the cathode to be drawn away, the operation occurs in a range below the saturation range. Operation in this range may be spoken of as operation below saturation.

A change in the temperature of the cathode in a hot cathode device embodying my invention will produce no change in the discharge when the operation is below saturation, even though the ionization voltage is materially exceeded. That is, the current-voltage curve is not changed by a change in the cathode temperature under such conditions.

The discharge in devices embodying my invention is practically independent of the pressure when the pressure is below a certain value which depends upon the size and shape of the device and upon the current and voltage of the discharge.

Page 5:

Line 22, cancel the insertions made by the amendments of December 17, 1914, and May 19, 1917.

Line 27, cancel the insertion made by the amendment of December 17, 1914.

Line 27, also cancel the long insertion made by the amendment of January 29, 1917, and

Line 27, also cancel the insertion made by the amendment of May 19, 1919.

Line 27, insert after the period the following:

N8

In a device in which the conduction of current is purely electronic, and the effect of positive ions is negligible, the conduction of current is governed, over a certain range, on the one hand by the effect of the impressed voltage, which tends to propel the electrons across the vacuous space, and on the other hand by the mutual repulsion of the electrons in the space, which tends to limit or inhibit the current. This last mentioned phenomenon, the current limiting effect of the electric field of the electrons on each other, termed the "space charge effect", is discussed and analyzed by me in a paper read before the Physical Society on October 18, 1913, which was abstracted in the Physical Review for November, 1913, and published in full in the Physical Review for December, 1913, and again published in somewhat modified form in the Physikalische Zeitschrift for April 1, and May 15, 1914. It is the basis of the 3/2 power law referred to herein.

The geometric proportions of the device also affect the amount of current which will pass with a given voltage, but as these conditions remain fixed for a given device they may be represented by a constant in an equation expressing the relation between the current and the voltage.

As stated above, the current (I) in the particular device described herein, when operating below saturation, will vary with the 3/2 power of the voltage (V), the equation being:

Hand set

$$I = aV^{3/2} \quad (a \text{ being a constant})$$

center

As is well known, if we produce a logarithmic graph of any equation in which one variable of the equation varies as a power of the other variable, as for example, an equation of the general form $y = x^n$, (as by plotting logarithms of x as abscissae and logarithms of y as ordinates) we find that this graph is a straight line. Hence the relation between current and voltage in a device operating below saturation and by pure electronic conduction independent of gas ionization may be expressed by the statement that when with a sufficient electron emission the logarithms of the current values transmitted between cathode and anode are plotted as ordinates against the logarithms of the respective voltages impressed between cathode and anode as abscissae, the slope of the line obtained does not ordinarily increase for increasing voltage values over a working range of voltages extending materially above the ionization voltages.

A substantial amount of positive ionization ordinarily causes the logarithmic plot of the current with respect to the voltage to bend upwardly and away from the 3/2 power line when the ionizing voltage is materially exceeded. The absence of a bend in the logarithmic plot at voltages somewhat above the ionization voltage is ordinarily a reliable indication that the tube is a pure electron discharge tube, though saturation complete or partial at voltages somewhat greater than the ionization voltages may prevent such a bend in the plot of an ionizing tube.

As above indicated, one of the indications of positive ionization is the occurrence of erratic readings in measuring devices connected in circuit with an electron discharge device under observation. Such erratic readings, of course, will produce a sudden change or discontinuity in the logarithmic graph plotted as above described, and any such irregularities will be more manifest when observed as deviations from a straight line than when the readings are plotted directly.

The effect of positive ionization upon the magnitude of the discharge is especially marked in that region of operation where the current is limited by the space charge effect already discussed, and changes in curvature of the discharge characteristic may occur as indicated unaccompanied by any visible evidence of ionization such as blue glow or the like. At saturation on the other hand, the discharge is ordinarily much less sensitive, and in fact the discharge may actually exhibit marked blue glow effects along with a flat or straight saturation curve.

Page 8.

Line 28, after "invention" cancel the insertion of March 14, 1916.

Line 31, before "with" insert ~~--~~, and such devices may be made which will operate without substantial positive ionization at voltages far above the ionization voltages -

Line 32, cancel "minute"

Line 32, cancel "above referred"

Page 4:

Line 1, cancel "to" and substitute - of the prior art -

Line 1, after "operable" insert - without substantial positive ionization -

Line 1, after the amendment of April 29, 1916, change the period to a comma and add - though the voltage is materially above the ionization voltages -

Cancel lines 2 to 17 inclusive.

Page 6:

Line 5, cancel the amendment added by amendment of March 29, 1915, and substitute the following:

- It will be noted that both in Figure 1 and Figure 2 the electrons are afforded a short and direct path from the cathode to the anode and that this path is so related to the position of the walls of the tube as to minimize the tendency for electrons to pass to the walls of the tube. In such a tube electron bombardment of the walls of the tube is avoided, together with the heating of such walls and the secondary emission of electrons therefrom which said bombardment causes. The energy of the discharge is delivered mainly, or entirely, at the anode, anodes, or upon other interior members instead of at the walls of the tube. -

n10

Page 6:

Line 21, cancel "In fact," and begin "the" with a capital letter.

n11

Line 21, after "heating" insert -, especially of solid anodes such as shown in Figure 2, -

Cancel lines 24 to 31 inclusive, and insert:

n12

- Bombardment is a very effective means of removing occluded gas from anodes. -

Page 7:

Lines 25 to 27, cancel the sentence "In the case", etc. through "may suffice"

Line 27, make the sentence beginning "After the metal" begin a new paragraph.

Line 28, before "take" insert - readily -

Line 31, cancel "without further" and substitute - with less -

Page 8:

Lines 9 and 10, correct the spelling of "permissible"

Line 12, place a comma after "gas" (second occurrence)

Line 22, cancel "copending"

Line 23, after "concurrently herewith" inserted by amendment of April 30, 1914, insert - upon which Patent 1,273,783 was granted on July 23, 1918. -

n13

Line 24, correct the spelling of "assymmetric"

5 5

Page 10:

Line 8, insert after "described" - and claimed -

At the end of the specification before the preamble to the claims add the following:

copies

Residual gas left in a tube when it is sealed off or occluded gas driven off from the inner wall of the tube, or from the elec-

trodes, during the use of the tube, varies in pressure from time to time according to the condition of operation of the tube and may produce irregularities in the discharge when operating in the saturation region as well as when operating below saturation. The irregularities below saturation are due mainly to the disturbing effect of the resulting positive ions upon the space charge. The irregularities in the saturation region are due to changes in the rate of emission or liberation of electrons at the cathode. It is obvious that the advantages of stable and reproducible operation and freedom from destructive bombardment of the cathode by positive ions, which advantages are severally or collectively to be secured by the means hereinabove described, are not limited to operation below saturation but are also important in operation in the saturation region.

N14

The positive ionization herein referred to is that positive ionization which occurs as the result of collisions between electrons and gas molecules in the space between the electrodes and causes, as by producing changes in space charge, unstable and nonreproducible operation.

At the end of the original specification, cancel claims 10 and 11.

In the amendment of December 26, 1915:

Substitute for claim 12:

N15

10. An electrical discharge device comprising a gas-tight envelope, an electron-emitting cathode, a cooperating anode, and a discharge-varying conductor, the space in said envelope being evacuated to below the pressure at

N15

which deleterious gas ionization takes place, constituting a device in which the current passed when operated below saturation and over a working range of voltage materially above the ionization voltages is controlled by space charge substantially unaffected by positive ionization.

a' follows

Insert a

Cancel claim 13.

Renumber claim 14 as claim 11.

Substitute for claim 15:

n16

a 12. An electrical discharge device, comprising a gas-tight envelope, an electron emitting cathode, an anode deprived of ionizable gas and a discharge controlling conductor, the space in the envelope being evacuated to a pressure not substantially in excess of a few hundred thousandths of a millimeter of mercury, said device being characterized by the fact that when operated below saturation and materially above the ionization voltages, the current is controlled by space charge substantially unaffected by positive ionization.

In the amendment of April 30, 1914:

Cancel claim 16.

In the amendment of December 17, 1914:

Substitute for claim 1[illegible]:

13. An electrical discharge device comprising a gas-tight envelope, an electron emitting cathode, a cooperating anode, the space and materials in said envelope being sufficiently free of gas so that substantially no positive ionization occurs when the impressed voltage is as high as 60 volts, and the current over a working range of voltage up to 60 volts varies with the 3/2 power of the impressed voltage.

Cancel claim 18.

Substitute for claims 19 to 22 inclusive:

n 18

4 14. An electrical discharge device comprising a gas-tight envelope, a cathode adapted to be heated to incandescence, an anode from which substantially no ionizable gas can be evolved at operating voltages up to 100 volts with currents up to 1 milliampere, the envelope so shaped and the electrodes so positioned as to substantially avoid secondary electron emission from the wall of the envelope, the space in said envelope being evacuated to a pressure not in substantial excess of a few hundred thousandths of a millimeter of mercury.

15. A device comprising a gas-tight envelope, a cathode adapted to be heated to incandescence, an anode from which no ionizable gas can be evolved at operating voltages up to about 200 volts with operating currents up to about five milliamperes, the space in said envelope being evacuated at a pressure not in substantial excess of a few hundred thousandths of a millimeter of mercury, said device being characterized by the fact that with currents up to about five milliamperes at voltages up to about 200 volts, evidences of positive ionization are substantially absent and the current over a working range below saturation varies with the 3/2 power of the voltage.

16. An electrical discharge device comprising a sealed envelope, an incandescent cathode, and a tungsten anode, said anode deprived of ionizable gas disengageable by electron bombardment, and the space in said envelope being evacuated to a sufficiently low pressure so that current flow produces substantially no phenomena of positive ionization when the impressed voltage is as high as 100 volts and the current is as large as 1 milliampere,

and the energy of the discharge is delivered mainly upon said anode.

17. An electron discharge apparatus comprising an envelope, an electron emitting cathode, and an anode, said anode being free of gas disengageable by electron bombardment and said envelope being sufficiently free of gas, so that conduction of current can take place in the evacuated space independently of gas ionization at voltages materially above the ionizing voltages with currents of more than one-tenth of a milliampere, and with the energy of the discharge delivered mainly at said anode.

In the amendment of March 10, 1916:

Cancel claims 24 and 25.

Substitute for claims 26 and 27:

9

19

18. An electrical discharge device comprising a sealed envelope, a cathode, means for producing emission of electrons at said cathode independently of the operating voltage, an anode, and discharge varying means independent of the cathode and anode, said device being freed from gas to such extent that the same is operable to transmit current at an impressed voltage at least as high as about 200 volts without evidences of substantial positive ionization.

19. An electrical discharge device comprising a sealed envelope, an incandescent cathode, an anode and discharge-varying means independent of the cathode and anode, the gas residues in said device being so small that the conduction of current is stable and reproducible over a range of voltage materially above the ionization voltages with currents in excess of one milliampere and with the energy of the discharge delivered mainly upon electrodes.

In the amendment of April 29, 1916:

Cancel claims 25 and 28.

In the amendment of June 22, 1916:

Cancel claims 29, 30, 31 and 32.

In the amendment of January 29, 1917:

Cancel claims 33 and 34.

Change the number of claim 35 to 20.

Cancel claims 36 and 37.

In the amendment filed May 19, 1919:

Claim 4, line 4, from the end, cancel the comma.

Claim 7, line 7, change "electrons" to

- electrodes -

In the amendment filed March 15, 1921:

Change the numbers of claims 38 and 39 to

21 and 22, respectively.

Add the following claims:

20
n

- 23. A discharge device comprising a tube and electrodes therein, ~~one~~ of which is a cathode, the discharge passing in the main directly between electrodes, the degree of evacuation and the relation of the parts of the device being such that the device is capable of being so operated below saturation and at voltages materially higher than the ionization voltages, that the slope or location of the logarithmic line of current with respect to voltage is not changed by changes in the temperature of the cathode.-

- 24. A discharge device comprising a tube and electrodes therein, one of which is a cathode adapted to be heated and to emit electrons thereby, the discharge passing directly between electrodes, the degree of evacuation and the relation of the parts of the device being such that the device is capable of being so operated below saturation and at voltages materially higher than the ionization voltage, that the plot of the current against the voltage is not changed with changes in the temperature of the cathode.

25. A discharge device comprising a sealed off envelope having therein a cathode adapted to be heated independently of the discharge and to deliver electrons thereby, and an anode, the inner wall of the envelope and the electrodes being sufficiently free of occluded gas, and the free gas within the envelope being such, so that the finished device is capable of sustained operation below saturation in a stable and reproducible manner with currents of more than one milliampere at voltages materially higher than the ionization voltages and with the energy of the discharge delivered mainly at an electrode or electrodes.

26. A discharge device comprising a sealed off envelope and electrodes therein, the envelope being shaped and the electrodes located so that the energy of the discharge is delivered mainly upon one or more of the electrodes, the inner wall of the envelope and electrodes being so free from occluded gas and the pressure in the tube being sufficiently low, with respect to the spacing of the electrodes and the energy of the discharge, so that the device is capable of passing a sustained discharge of one tenth of a milliampere at forty volts, without developing any substantial positive ionization effects.

27. A discharge device comprising a sealed off envelope and electrodes therein, one of which is a cathode adapted to be heated independently of the discharge

and to emit electrons thereby, the inner wall of the envelope and the electrodes being so free from occluded gas that the device is capable of passing a sustained discharge of one milliampere at fifty volts with the energy of the discharge delivered mainly at an electrode or at electrodes without liberating any substantial amount of gas into the space within the envelope.

28. A discharge device comprising a sealed-off envelope and electrodes therein, one of which is a cathode adapted to be heated independently of the discharge and to emit electrons thereby, the inner wall of the envelope and the electrodes being so free from occluded gas that the device is capable of passing a sustained discharge of two milliamperes at one hundred volts with the energy of the discharge delivered mainly at an electrode or at electrodes without liberating any substantial amount of gas into the space within the envelope.

29. An electrical discharge device comprising a gas-tight envelope, a cathode adapted to be heated to incandescence, an anode from which substantially no ionizable gas can be evolved at operating voltages up to forty volts with currents up to one-tenth milliampere, the envelope so shaped and the electrodes so positioned as to substantially avoid secondary electron emission from the wall of the envelope, the space in said envelope being evacuated to a pressure not in substantial excess of a few hundred thousandths of a millimeter of mercury.

30. In the process of producing a discharge device, removing the occluded gas from the interior surface of the envelope thereof and from the electrodes to such an extent that the finished sealed-off device will operate, without liberating any substantial amount of gas into the

space within the envelope, at voltages materially above the ionization voltage with currents greater than one milliampere and with substantially all the energy of the discharge delivered to an anode or anodes.

31. In the process of producing a hot cathode discharge device, treating the interior surface of the envelope and the operating parts to liberate therefrom occluded gas, and removing from the envelope gas liberated by said treatment and free gas originally contained therein, continuing these operations until the occluded and original free gas is so thoroughly removed as to enable the finished sealed-off device to operate below saturation in a stable and reproducible manner at a voltage above fifty volts and with a current greater than one milliampere and with the energy of the discharge delivered mainly at one or more anodes.

32. The process of producing a discharge device which consists in treating the envelope and enclosed parts thereof to liberate gas therefrom and removing from the envelope gas which is thereby liberated and free gas originally contained in the envelope, the treatment being sufficiently powerful and being sufficiently prolonged and the removal of the liberated and original free gas from the envelope being sufficiently thorough, so that the finished sealed-off device is capable of sustained operation substantially without positive ionization at voltages as high as one hundred volts with currents as great as one milliamper, and with substantially the entire energy of the discharge delivered upon the anode or anodes of the device.

REMARKS

Claims 1 to 9 inclusive, and claims 11, 20, 21 and 22, were the counts in the interference and have not been changed except to correct obvious clerical errors in claims 4 and 7.

Claim 10 and claims 12 to 19 inclusive, are respectively prior claims 12, 15, 17, 19, 20, 21, 22, 26 and 27, all amended to more clearly or more accurately define the invention with the aid of the light thrown thereon during the interference.

Claims 23 to 32 inclusive, are new claims which are believed to define the invention so clearly as to render discussion thereof here unnecessary.

Prior claims 10, 11, 13, 16, 18, 23, 24, 25, 28 29, 30, 31, 32, 33, 34, 36 and 37 have been cancelled, some because they did not accurately or sufficiently define the invention and others because they did not state the invention as clearly as do the remaining claims as now presented. Among the cancelled claims are the claims which were withdrawn in the interference and which the Law Examiner refused to add to the issue or dissolved out of the same.

The case is believed to be in condition for allowance and an early allowance is requested.

Respectfully submitted,

Alexander S Lunt

Serial No. 84242

Div. 8

DEPARTMENT OF COMMERCE
UNITED STATES PATENT OFFICE
WASHINGTON Sep. 23, 1925.

Irving Langmuir, Assor to General Electric Company, a corp. of N. Y.

Sir: Your **APPLICATION** for a patent for an **IMPROVEMENT** in ELECTRICAL DISCHARGE APPARATUS AND THE PROCESS OF PREPARING AND USING THE SAME filed Oct.16,1913 has been examined and **ALLOWED** (32 claims).

The final fee, **TWENTY DOLLARS**, must be paid not later than **SIX MONTHS** from the date of this present notice of allowance. If the final fee be not paid within that period, the patent on this application will be withheld, unless renewed within two years after the date of this notice with an additional fee of $20, under the provisions of Section 4897, Revised Statutes.

The office delivers patents upon the day of their date, and on which their term begins to run. The printing, photolithographing, and engrossing of the several patent parts, preparatory to final signing and sealing, will require about four weeks, and such work will not be undertaken until after payment of the necessary fee.

When you send the final fee you should also send, **DISTINCTLY AND PLAINLY WRITTEN**, the name of the **INVENTOR, TITLE OF INVENTION, AND SERIAL NUMBER AS ABOVE GIVEN, DATE OF ALLOWANCE** (which is the date of this circular), **DATE OF FILING**, and, if assigned, the **NAMES OF THE ASSIGNEES.**

If you desire to have the patent issue to **ASSIGNEES**, an assignment containing a **REQUEST** to that effect, together with the **FEE** for recording the same, must be filed in this office on or before the date of payment of final fee.

After issue of the patent uncertified copies of the drawings and specifications may be purchased at the price of **TEN CENTS EACH**. The money should accompany the order. Postage Stamps will not be received.

Final fees will **NOT** be received from other than the applicant, his assignee or attorney, or a party in interest as shown by the records of the Patent Office.

Respectfully,

Thomas E. Robertson
Commissioner of Patents.

Alexander D. Lunt.
Schenectady,
New York.

Patented Oct. 20, 1925. **1,558,436**

UNITED STATES PATENT OFFICE.

IRVING LANGMUIR, OF SCHENECTADY, NEW YORK, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

ELECTRICAL DISCHARGE APPARATUS AND PROCESS OF PREPARING AND USING THE SAME.

Application filed October 16, 1913, Serial No. 795,610. Renewed March 14, 1916. Serial No. 84,342.

To all whom it may concern:

Be it known that I, Irving Langmuir, a citizen of the United States, residing at Schenectady, county of Schenectady, State of New York, have invented certain new and useful Improvements in Electrical Discharge Apparatus and Processes of Preparing and Using the Same, of which the following is a specification.

The present invention relates to electrical vacuum discharge devices, and it comprises devices in which the electrical current is carried by negative charges called electrons, emanating from the cathode, independently of gaseous ionization such as occurring, for example, in the ordinary Roentgen tube.

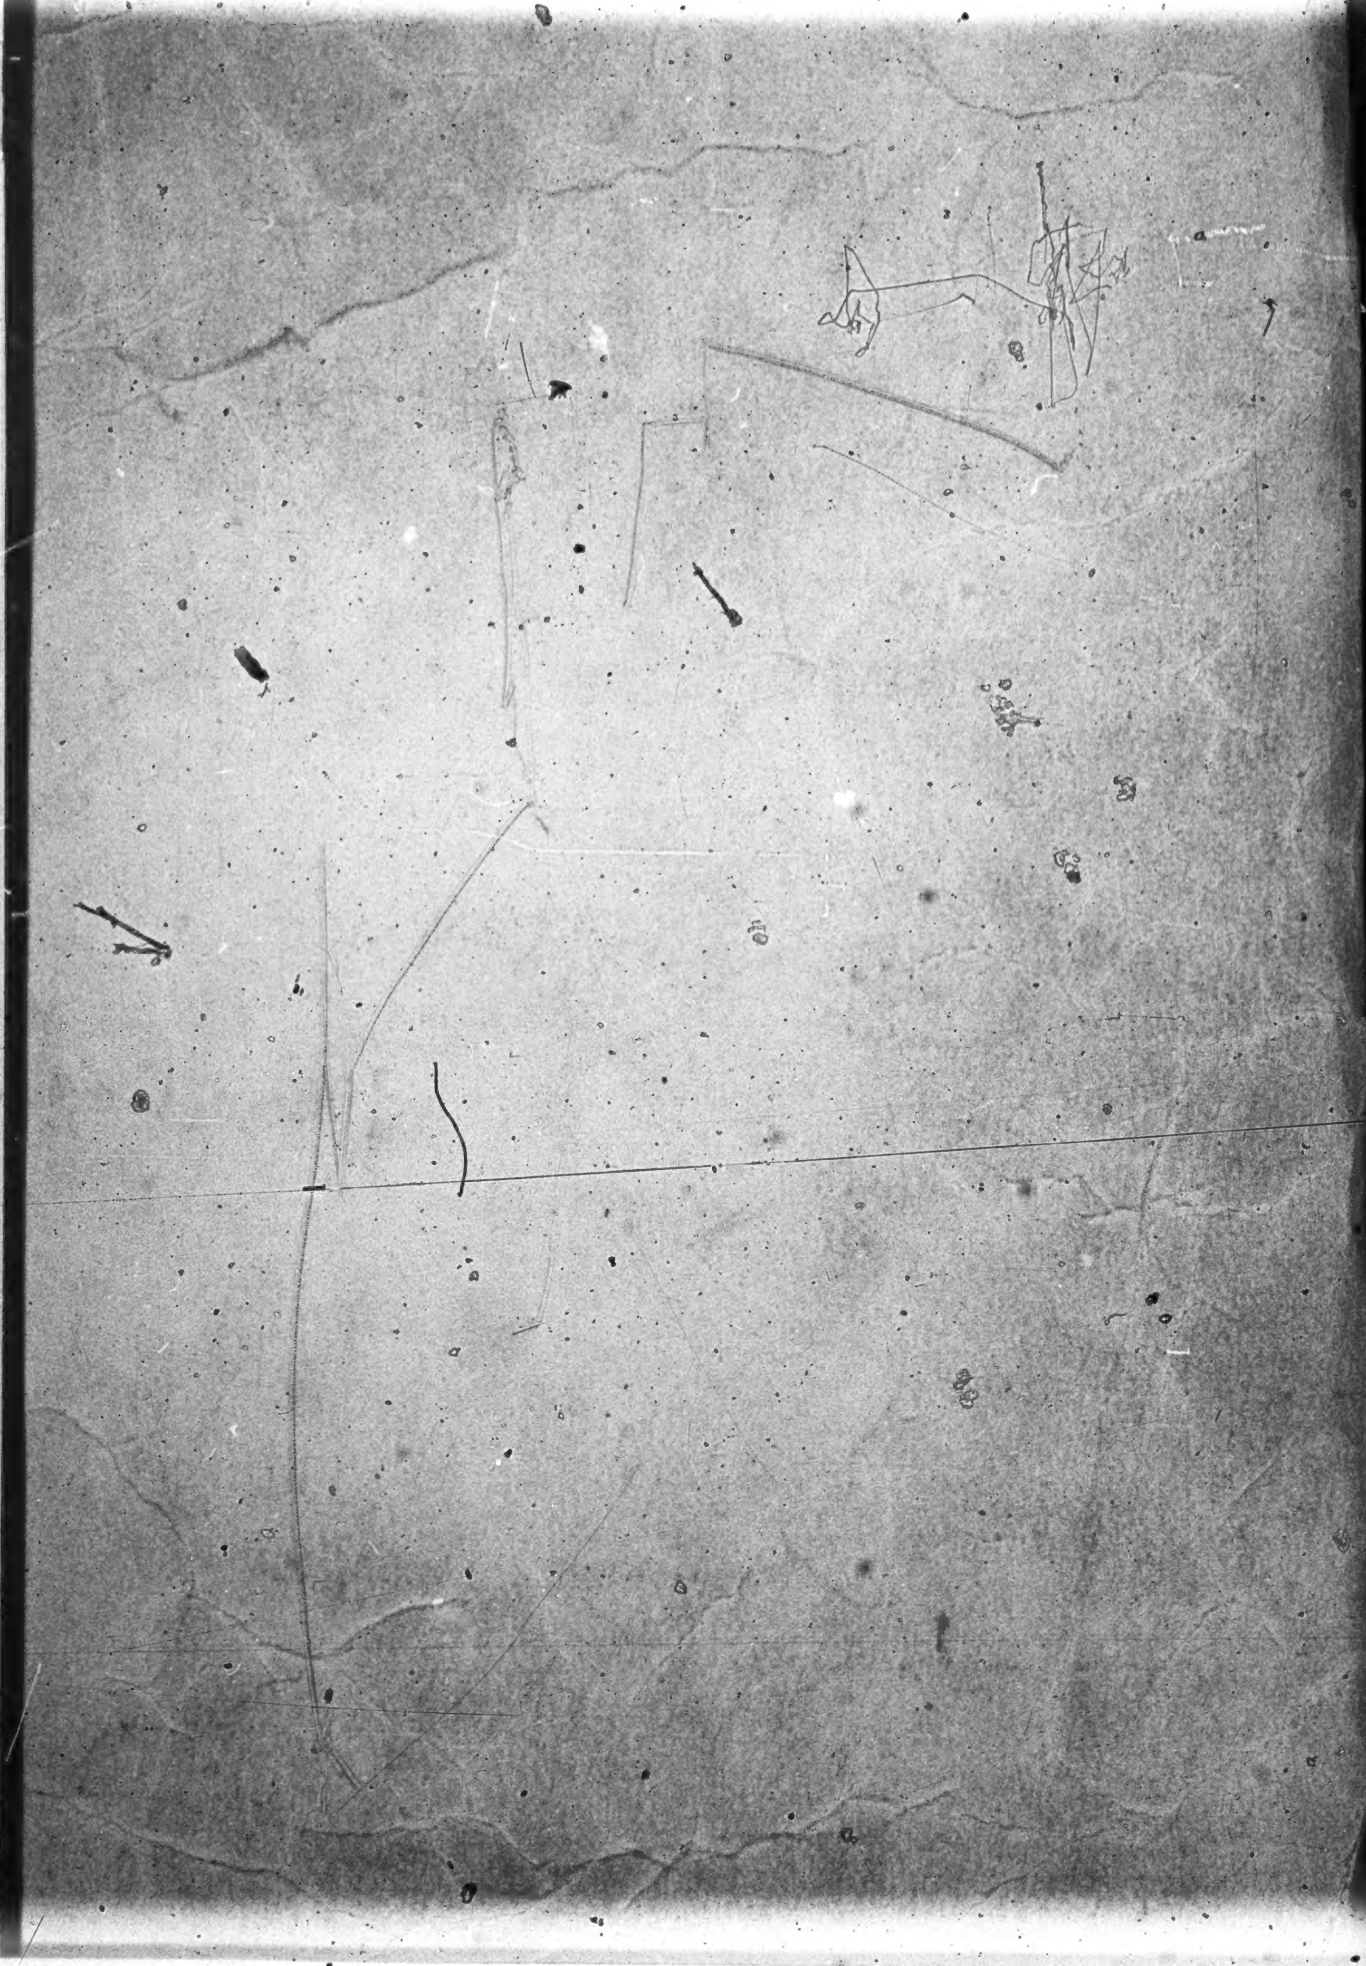
My present invention comprises improvements in electron-discharge apparatus which make possible a high load capacity and operation with the highest voltages but the invention is also applicable and useful for moderate loads and moderate voltages. The novel features of my invention will be pointed out with greater particularity in the appended claims.

Figs. 1 and 2 of the accompanying drawings, Fig. 2 being a partial view, illustrate two types of discharge devices embodying my invention; Fig. 3 is a fragmental view showing a cathode construction, and Figs. 4 and 5 are diagrams of electrical systems illustrating certain applications of my electron discharge tubes.

In order to distinguish electron discharge devices made in accordance with my invention from the prior art, I will explain briefly the character of a pure electron discharge as distinguished from a discharge through ionized gas. In a Geissler tube, and in a Roentgen or Crookes tube the conduction of current is accompanied by and depends upon gas ionization. Without a certain minimum amount of gas a Roentgen X-ray tube ceases to operate and as this minimum is approached the resistance of the tube steadily increases.

The passage of an electric current across a tube ordinarily involves the movement of negative charges called electrons which, under the influence of the impressed voltage, pass from the cathode to the anode through the vacuous space. If these electrons when moving above a certain velocity collide with gas molecules they tend to ionize the molecules, splitting them up into electrons and larger and more slowly moving ions. Under these circumstances the phenomena of conduction across the tubes are the result of the action and interaction of the electrons and the ions; these phenomena are in general erratic and non-reproducible. The cathode under these conditions is disintegrated, technically it is "sputtered", which causes its rapid destruction. As gas ionization continues at higher voltages a blue glow may appear. The bombardment of the cathode by positive ions also causes heating of the cathode. The ionization of gases at low pressures by collision with electrons occurs at definitely determinable voltages, these voltages being known as the ionization voltages. These voltages are different for different gases. In the case of gases such as nitrogen, hydrogen, oxygen, argon, helium and neon, they are of the order of magnitude of fifteen to twenty-five volts.

The phenomena above described as being characteristic of devices involving gas ionization are taken advantage of in an incandescent cathode device with three electrodes known as the "Audion." This device has been used as a receiver for radio-telegraphy and depends in its operation upon the rapid change of the discharge current when gas ionization begins. This point depends upon various accidental conditions which cause such irregularities in the operation of various devices apparently identical that sometimes only one of a considerable number can be used. Ordinarily the gas ionization in the audion begins to be important somewhere between 20 and 30 volts. Another discharge device previously used to some extent was the Fleming valve. This was a two-electrode tube which, so far as I am aware, was always used at voltages well below the voltages at which positive ionization by collision occurs. It was not evacuated in such a manner as to permit it to be used at voltages materially above these ionization voltages without manifesting substantial positive ionization effects. No prior hot cathode devices are known to me operating with currents as great as about 5 milliamperes with voltages as high as about 200 volts; indeed no prior discharge devices are known to me operating in a practically usable manner and without substantial positive ionization



effects with currents as great as about one-tenth of a milliampere with voltages as high as about forty volts.

In devices made in accordance with my invention gas ionization is either entirely absent or is negligible and a discharge takes place which is distinct in its characteristics from the described discharge taking place in an ionized gas. The cathode is not heated by the discharge itself. Blue glow, glass fluorescence and in fact all readily visible indications of a discharge are ordinarily absent. In most devices of simple construction which embody my invention, the discharge current passing through a given space with the cathode at a sufficiently high temperature with respect to the voltages employed, varies directly with the 3/2 power of the impressed voltages. This 3/2 power law can be readily derived mathematically for a tube in which there is substantially no positive ionization on the assumption that the whole surface of the cathode is at a uniform potential; that the electrons escape from the cathode with negligible velocities and that the walls of the tube do not carry appreciable electric charges.

In most simple devices embodying my invention, these conditions are so well fulfilled that the current does vary in proportion to the 3/2 power of the voltage over wide ranges of voltage above the ionizing voltages. This means that if the logarithm of the current is plotted against the logarithm of the voltage, the resulting plot is a straight line whose slope is 3/2. Or, in many cases it is more convenient to make use of the equivalent relation, that the 2/3 power of the current plotted as ordinates against the anode voltages as abscissae gives a straight line.

In devices in which there is substantial positive ionization, on the other hand, even when the pressure of gas are so low that only very small currents could be carried by positive ions, the currents begin to increase with voltage more rapidly than according to the 3/2 power law as soon as the anode voltage materially exceeds the ionizing potential of the gas.

In devices embodying my invention which have more than two electrodes, or with special constructions as where the cathode is a filament, so long that it cannot be considered an equi-potential surface, the 3/2 power law may be more or less masked. However, the effects thus introduced will be readily understood by those skilled in the art, and appropriate methods of identifying the pure electron discharge can easily be found corresponding to the special construction. For example, when such tubes have more than two electrodes and the temperature of the cathode is sufficiently high with respect to the voltages employed, the discharge will usually be characterized by a linear relation between the 2/3 power of the total electron current from the cathode and the voltage applied to any other electrode, the remaining electrodes being kept at constant potential. Another test that can often be made with a three electrode tube is to connect the grid directly to the anode, or to the negative end of the cathode, and observe whether the current varies as the 3/2 power of the voltage.

If for a given cathode temperature the voltage is sufficiently high to cause all of the electrons emitted or liberated at the cathode to be drawn away, then a further increase in voltage produces substantially no change in the current. The current thus determined is called the saturation current, and the range of operation in which the current is substantially independent of the voltage or approaches this condition may be called the saturation range or more briefly designated merely as saturation. If for a given cathode temperature the voltage is not high enough to cause all of the electrons which are emitted or liberated at the cathode to be drawn away, the operation occurs in a range below the saturation range. Operation in this range may be spoken of as operation below saturation.

A change in the temperature of the cathode in a hot cathode device embodying my invention will produce no change in the discharge when the operation is below saturation, even though the ionization voltage is materially exceeded. That is, the current-voltage curve is not changed by a change in the cathode temperature under such conditions.

The discharge in devices embodying my invention is practically independent of the pressure when the pressure is below a certain value which depends upon the size and shape of the device and upon the current and voltage of the discharge.

As distinguished from discharges in the presence of positive ionization, the pure electron discharge is characterized by regularity and reproducibility with given conditions. In a device in which the conduction of current is purely electronic, and the effect of positive ions is negligible, the conduction of current is governed, over a certain range, on the one hand by the effect of the impressed voltage, which tends to propel the electrons across the vacuous space, and on the other hand by the mutual repulsion of the electrons in the space, which tends to limit or inhibit the current. This last mentioned phenomenon, the current limiting effect of the electric field of the electrons on each other, termed the "space charge effect," is discussed and analyzed by me in a paper read before the Physical Society on October 18, 1913, which was abstracted in the Physical Review for November, 1912, and published in full in the Physical Review for December, 1913, and again published in somewhat modified form in the Physikalische Zeitschrift for April 1, and May 15, 1914. It is the basis of the 3/2 power law referred to herein.

The geometric proportions of the device also affect the amount of current which will pass with a given voltage, but as these conditions remain fixed for a given device they may be represented by a constant in an equation expressing the relation between the current and the voltage.

As stated above, the current (I) in the particular device described herein, when operating below saturation, will vary with the 3/2 power of the voltage (V), the equation being:

$$I = aV^{3/2}, \text{ (a being a constant)}$$

As is well known, if we produce a logarithmic graph of any equation in which one variable of the equation varies as a power of the other variable, as for example, an equation of the general form $y = ax^n$, (as by plotting logarithms of x as abscissæ and logarithms of y as ordinates) we find that this graph is a straight line. Hence the relation between current and voltage in a device operating below saturation and by pure electronic conduction independent of gas ionization may be expressed by the statement that when with a sufficient electron emission the logarithms of the current values transmitted between cathode and anode are plotted as ordinates against the logarithms of the respective voltages impressed between cathode and anode as abscissæ, the slope of the line obtained does not ordinarily increase for increasing voltage values over a working range of voltages extending materially above the ionization voltages.

A substantial amount of positive ionization ordinarily causes the logarithmic plot of the current with respect to the voltage to bend upwardly and away from the 3/2 power line when the ionizing voltage is materially exceeded. The absence of a bend in the logarithmic plot at voltages somewhat above the ionization voltage is ordinarily a reliable indication that the tube is a pure electron discharge tube, though saturation complete or partial at voltages somewhat greater than the ionization voltages may prevent such a bend in the plot of an ionizing tube.

As above indicated, one of the indications of positive ionization is the occurrence of erratic readings in measuring devices connected in circuit with an electron discharge device under observation. Such erratic readings, of course, will produce a sudden change or discontinuity in the logarithmic graph plotted as above described, and any such irregularities will be more manifest when observed as deviations from a straight line than when the readings are plotted directly.

The effect of positive ionization upon the magnitude of the discharge is especially marked in that region of operation where the current is limited by the space charge effect already discussed, and changes in curvature of the discharge characteristics may occur as indicated unaccompanied by any visible evidence of ionization such as blue glow or the like. At saturation on the other hand, the discharge is ordinarily much less sensitive, and in fact the discharge may actually exhibit marked blue glow effects along with a flat or straight saturation curve.

Devices made in accordance with my invention may be used for various technical purposes, such as relaying and detecting currents, producing oscillations and rectifying alternating currents, and such devices may be made which will operate without substantial positive ionization at voltages far above the ionization voltages with currents thousands of times greater than the currents at which the devices of the prior art were operable without substantial positive ionization. Devices made and operated in accordance with my invention are capable of transmitting currents materially exceeding one-tenth of a milliampere without causing positive ionization to take any essential part in the operation of the device, though the voltage is materially above the ionization voltages.

Before describing the method of preparing my new type of apparatus, I will describe the structure of the apparatus illustrated by Figs. 1 to 3.

As shown in Fig. 1 the various parts of the apparatus may be mounted in a tube, or envelope 1, upon a pedestal 2, similar to the mount used in incandescent lamps. The cathode 3 is centrally located and may consist of a short straight filament not shown in Fig. 1, but indicated by the position of terminals 5, 6, and shown plainly in Fig. 3. The cathode shown in Fig. 2 consists of a V-shaped conductor. Either form may be used, the particular form of cathode being ordinarily determined by convenience of construction. Preferably the cathode conductor is held taut by a spring 7 to avoid contact of the cathode conductor with the grid by sagging when the metal is expanded at a high temperature. The filament 3 is mounted between two oppositely disposed supports, 9, 9′, in this case constituting a closed loop, which may consist of insulating material, such as glass or quartz, but in some cases may to advantage consist of metal. Upon this frame-work is wound a discharge-varying conductor 10, ordinarily called a grid. The turns of the wire are closely adjacent to each other and are also very closely adjacent to but are out of contact with the incandescent cathode. By means of this grid 10 potential may be applied to exert a static control upon the movements of the electrons. A negative potential applied on the grid reduces the flow of current from cathode to anode in proportion to the degree of negative charge. A positive grid potential assists and directs the flow of current from cathode to anode in proportion to the degree of its charge.

The supporting framework for the cathode and grid is attached to a rod 11, mounted upon the stem of the tube. Adjacent to the cathode and grid is the anode 12 which in the present case has been indicated as consisting of a wire strung in a zig-zag manner over hooks 13 upon fork-shaped supports 14 and 15, but it is not necessary that it should assume this particular form. Both anode and grid preferably consist of tungsten, but other refractory metals may be used. By constituting the anode a continuous conductor it can be conveniently heated by passage of current during evacuation of the device and for this purpose is attached to leading-in conductors 16 and 17. The grid is indicated in Fig. 1 as being attached to leading-in conductors 18 and 19 at opposite ends, although but one terminal is ordinarily necessary.

In some cases it is desirable to use a plate shaped anode; Fig. 2 illustrates such an arrangement suitable particularly for rectifying alternating current. The tube itself and other extraneous parts have not been shown in Fig. 2, as they are similar to Fig. 1. The cathode construction has already been referred to and the anodes 20 and 21 also preferably consist of tungsten and may be connected electrically with each other. Current connections are made by conductors 22, 23, the supports 24, 25 being merely indicated. It will be noted that both in Figure 1 and Figure 2 the electrons are afforded a short and direct path from the cathode to the anode and that this path is so related to the position of the walls of the tube as to minimize the tendency for electrons to pass to the walls of the tube. In such a tube electron bombardment of the walls of the tube is avoided, together with the heating of such walls and the secondary emission of electrons therefrom which said bombardment causes. The energy of the discharge is delivered mainly, or entirely, at the anode, anodes, or upon other interior members instead of at the walls of the tube.

For the evacuation of the device the glass walls of the tube are carefully heated to as high a temperature as the glass will stand without softening and in general the most approved methods of incandescent lamp exhaust are used. The evacuation of the tube preferably while still heated is carried out by means of a suitable evacuating means, for example, a Gaede molecular pump, which removes vapors as well as gases. Chemical evacuating means such as electrically vaporized calcium or magnesium may also be used. Either before or during the evacuation the anodes may be heated, especially when the anodes are to be run at elevated temperature during the normal operation of the device. In this case the temperature is preferably carried close to brilliant incandescence. In the case of the structure shown in Fig. 1, the heating may take place by passing an electrical current through the wire 12. The heating, especially of solid anodes such as shown in Figure 2, may take place in a suitable vacuum furnace, the temperature preferably being raised to 2,500° C. or even higher. Bombardment is a very effective means of removing occluded gas from anodes.

The bombardment is carried out when the evacuation has proceeded to a high degree by applying a potential between the cathode 8 and the anode 12, Fig. 1, the value of which depends upon the character of the device. Care should be taken to use a voltage below that at which a blue glow appears as this indicates harmful gas ionization, and as already pointed out, sputtering and disintegration of the cathode accompanies or closely follows the blue glow phenomenon. The pump should be constantly operated to remove the gas. After the removal of the gas thus driven out the voltage impressed between the cathode and the anode, or anodes, as the case may be, is increased thereby driving out more gas. This process is continued step by step with a progressively higher voltage, the final voltage depending upon the character of the apparatus. In most cases the final voltage should be materially higher than the voltage at which the device is to be used in actual service. However, in the case of devices that use exceedingly high voltages, such as 50,000 volts or even higher, substantially all the gas may be removed from the anode without resorting to voltages higher than the normal operating voltage. In the case of a plate-shaped anode which cannot be readily heated by passage of current, the discharge voltage may be chosen great enough to convey sufficient energy to the anode to raise its temperature to redness or even higher, when the device is to be used with a discharge current adapted to heat the anodes.

After the metal has been freed from occluded gas reabsorption of gas will not readily take place even though it is exposed to the air or other gases. For example, anodes thus treated may be removed to other apparatus which then may be evacuated with less electron bombardment of the anode or anodes.

The evacuation of the device should be preferably carried to a pressure as low as a few hundredths of a micron, or even lower, but no definite limits can be assigned. The residual gas pressure should be below the value at which ionization by collision will take place at the given working voltage and current, with its accompanying phenomena of blue glow, disintegration of the cathode, and so forth. When the cathode and anode are located in close proximity and the discharge confined to the region between the same, the permissible pressure is higher than when the cathode and anode are at some distance. It is also true that when the anode has been carefully freed from gas, residual free gas, even if present in a sufficient amount to cause some gas ionization when the apparatus is first started, does little harm, as it is quickly removed by the gas clean-up effect when the device is operated.

Electron discharge apparatus thus provided with a gas-free pretreated anode or anodes, may be constructed to handle currents at a very high voltage by proper mechanical design of the parts subjected to static strains, suitable proportioning of the parts and so forth as described, for example, in my application Serial No. 795,600 filed concurrently herewith upon which Patent 1,273,788 was granted on July 23, 1918.

The asymmetric conductivity existing between the heated and unheated electrodes of a device of the character described may be utilized for various technical purposes. Reference has already been made to the rectification of current. As shown in Fig. 4 an electron discharge tube may be used for detecting electromagnetic waves in radio-telegraphy. As shown in this Fig. 4 the grid *g* and heated cathode *c* of an electron discharge tube 26 are connected respectively to the terminals of the secondary of a transformer 27, the primary of which is included in the antenna circuit 28. The antenna is grounded through a condenser 29 in the usual manner. The cathode *c* is heated by a local source of energy, as battery *b*. A battery 30 in the grid circuit 31 has its negative terminal connected to the grid *g*. A condenser 32 shunts the secondary of the loosely coupled transformer 27. The inductance of the transformer and the capacity of the condenser are adjusted to make the receiving circuit resonant to the frequency of the oscillations to be received. The oscillations set up by the incoming signals are superimposed upon the negative grid potential and causes a variation of current transmitted between cathode *c* and anode *a* by a local source of energy such as a battery 33 included in the local or plate circuit 34, 35, of the discharge tube. This circuit is connected to an ordinary telephone receiver 36, preferably shunted by means of a condenser 37, whereby the signals are detected.

Fig. 5 illustrates how an electron discharge tube may be used in a system for producing alternating current from direct current. The anode *a* and cathode *c* are connected respectively to conductors 38, 39, one of which includes a local source of energy, such as a battery 40. The terminals of these conductors are connected to an inductive coil 41. The cathode and grid *g* are also connected respectively by conductors 39 and 42 to a second inductive coil 43 which may be in a variable inductive relation to the coil 41. As soon as a flow of current starts in the plate circuit 38, 39, current is induced in the coil 43 of the grid circuit 39, 42. When by reason of this current the grid becomes negatively electrified, the flow of current in the plate circuit is reduced, and as the plate current decreases the grid electrification changes to positive, which again allows the current in the plate circuit to increase. These changes take place with a frequency depending on the electrical characteristics of the circuits. Across the grid circuit 39, 42, of the discharge tube, in some cases is connected a condenser 44, the capacity of which may be varied to control the frequency of the oscillations set up by the system. The oscillations may be transformed to higher or lower voltage by a transformer coil 45 to the terminals of which are connected transmitting conductors 46, 47. The system shown in Fig. 5 is described and claimed in a copending application, Serial No. 797,-987, filed October 29, 1913.

Residual gas, left in a tube when it is sealed off or occluded gas driven off from the inner wall of the tube, or from the electrodes, during the use of the tubes, varies in pressure from time to time according to the conditions of operation of the tube and may produce irregularities in the discharge when operating in the saturation region as well as when operating below saturation. The irregularities below saturation are due mainly to the disturbing effect of the resulting positive ions upon the space charge. The irregularities in the saturation region are due to changes in the rate of emission or liberation of electrons at the cathode. It is obvious that the advantages of stable and reproducible operation and freedom from destructive bombardment of the cathode by positive ions, which advantages are severally or collectively to be secured by the means hereinabove described, are not limited to operation below saturation but are also important in operation in the saturation region.

The positive ionization herein referred to is that positive ionization which occurs as the result of collisions between electrons and gas molecules in the space between the electrodes and causes, as by producing changes in space charge, unstable and non-reproducible operation.

What I claim as new and desire to secure by Letters Patent of the United States, is:—

1. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the governing or limiting action on the space current due to the electric field of said electrons is substantially unaffected by positive ionization and by secondary electron emission from the walls of the tube.

2. A discharge tube having a cathode adapted to emit electrons and an anode adapted to receive said emitted electrons, the tube walls being fashioned or shaped to permit the direct passage of a useful proportion of said electrons from cathode to anode, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the space current is governed or limited by the electric field of said electrons substantially unaffected by positive ionization.

3. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that in that range the space current is governed by the combined effect of the electric field of said electrons and the potentials applied to said electrodes, the governing or limiting of the current being substantially unaffected by positive ionization and by secondary electron emission from the walls of the tube.

4. A discharge device comprising a tube and electrodes therein one of which is adapted to emit electrons, the degree of evacuation and the relation of the parts of the device being such that the device is capable of being so operated, when voltages materially higher than ionization voltages are impressed upon electrodes of the device and when the electron emission has any value such that the space current is below the saturation region at such voltages, that the slope of the line obtained by plotting the logarithms of values of said current as ordinates against the logarithms of the corresponding values of said impressed voltages as abscissae shows no increase for increasing voltage values.

5. A discharge device comprising a tube and electrodes therein one of which is adapted to emit electrons, the degree of evacuation and the relation of the parts of the device being such that the device is capable of being so operated, when voltages materially higher than ionization voltages are impressed on electrodes of the device and when the electron emission has any value such that the space current is below the saturation region at such voltages, that the line obtained by plotting the logarithms of any values of said current below the saturation region as ordinates against the logarithms of the corresponding values of said impressed voltages as abscissae is straight and continuous.

6. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated, when voltages materially higher than ionization voltages are impressed on electrodes of the tube and when the electron emission has any value such that the space current is below the saturation region at such voltages that said current varies as the three halves power of said impressed voltages.

7. A discharge device comprising a tube and electrodes therein one of which is an electron emitting cathode, the degree of evacuation of said device and the relation of the parts of the device being such that the device is capable of being so operated, when voltages materially higher than ionization voltages are impressed on electrodes of the device and when the electron emission is such that the space current is below the saturation region at such voltages that said current is substantially independent of the cathode temperature and unaffected by secondary electron emission from the walls of the tube.

8. A discharge tube having electrodes at least one of which is adapted to emit electrons, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of being so operated in a range below saturation and materially above ionization voltages that the space current is governed or limited by the combined effect of the electric field of said electrons and the potentials applied to said electrodes, substantially unaffected by positive ionization, the heating effect in the tube due to said current occurring substantially only at one or more of said electrodes.

9. A discharge tube having a cathode adapted to emit electrons, an anode adapted to receive electrons and tube walls fashioned or shaped so as to permit the free passage

of a useful proportion of said electrons from cathode to anode, the gas content or residue of said tube and the relation of the parts of the tube being such that the tube is capable of operation with stable and reproducible results substantially unaffected by positive ionization with currents of at least 5 milliamperes and with voltages of at least 200 volts.

10. An electrical discharge device comprising a gas-tight envelope, an electron-emitting cathode, a cooperating anode, and a discharge-varying conductor, the space in said envelope being evacuated to below the pressure at which deleterious gas ionization takes place, constituting a device in which the current passes when operated below saturation and over a working range of voltage materially above the ionization voltages is controlled by space charge substantially unaffected by positive ionization.

11. A high vacuum electron discharge device comprising an envelope, an incandescent cathode, and an anode, the space in said envelope being evacuated to such degree that the passage of current produces no appreciable, positive ionization when the impressed voltage is as high as 200 volts

12. An electrical discharge device, comprising a gas-tight envelope, an electron emitting cathode, an anode deprived of ionizable gas and a discharge controlling conductor, the space in the envelope being evacuated to a pressure not substantially in excess of a few hundred thousandths of a millimeter of mercury, said device being characterized by the fact that when operated below saturation and materially above the ionization voltages, the current is controlled by space charge substantially unaffected by positive ionization.

13. An electrical discharge device comprising a gas-tight envelope, an electron emitting cathode, a cooperating anode, the space and materials in said envelope being sufficiently free of gas so that substantially no positive ionization occurs when the impressed voltage is as high as 60 volts, and the current over a working range of voltage up to 60 volts varies with the 3/2 power of the impressed voltage.

14. An electrical discharge device comprising a gas-tight envelope, a cathode adapted to be heated to incandescence, an anode from which substantially no ionizable gas can be evolved at operating voltages up to 100 volts with currents up to 1 milliampere, the envelope so shaped and the electrodes so positioned as to substantially avoid secondary electron emission from the wall of the envelope, the space in said envelope being evacuated to a pressure not in substantial excess of a few hundred thousandths of a millimeter of mercury.

15. A device comprising a gas-tight envelope, a cathode adapted to be heated to incandescence, an anode from which no ionizable gas can be evolved at operating voltages up to about 200 volts with operating currents up to about five milliamperes, the space in said envelope being evacuated at a pressure not in substantial excess of a few hundred thousandths of a millimeter of mercury, said device being characterized by the fact that with currents up to about five milliamperes at voltages up to about 200 volts, evidences of positive ionization are substantially absent and the current over a working range below saturation varies with the 3/2 power of the voltage.

16. An electrical discharge device comprising a sealed envelope, an incandescent cathode, and a tungsten anode, said anode deprived of ionizable gas disengageable by electron bombardment, and the space in said envelope being evacuated to a sufficiently low pressure so that current flow produces substantially no phenomena of positive ionization when the impressed voltage is as high as 100 volts and the current is as large as 1 milliampere, and the energy of the discharge is delivered mainly upon said anode.

An electron discharge apparatus comprising an envelope, an electron emitting cathode, and an anode, said anode being free of gas disengageable by electron bombardment and said envelope being sufficiently free of gas, so that conduction of current can take place in the evacuated space independently of gas ionization at voltages materially above the ionizing voltages with currents of more than one-tenth of a milliampere, and with the energy of the discharge delivered mainly at said anode.

18. An electrical discharge device comprising a sealed envelope, a cathode, means for producing emission of electrons at said cathode independently of the operating voltage, an anode, and discharge varying means independent of the cathode and anode, said device being freed from gas to such extent that the same is operable to transmit current at an impressed voltage at least as high as about 200 volts without evidences of substantial positive ionization.

19. An electrical discharge device comprising a sealed envelope, an incandescent cathode, an anode and discharge-varying means independent of the cathode and anode, the gas residues in said device being so small that the conduction of current is stable and reproducible over a range of voltage materially above the ionization voltages with currents in excess of one milliampere and with the energy of the discharge delivered mainly upon electrodes.

20. An electrical device comprising the combination of a sealed evacuated envelope, a cathode adapted to be independently heated, and an anode within said envelope,

an external circuit connected to said electrodes, and a source of electro motive force applied to said circuit, the degree of vacuity and the electron emission of the cathode being so related to the potential of said source that the flow of current over a range of voltage materially above the ionization voltage is governed by the electric field of the electrons in the vacuous space and the potential applied to said electrodes, operatively independent of gas ionization.

21. Apparatus for controlling an electric current comprising a vacuum tube, an anode and an electron emitting cathode in the circuit of said current and within said tube, the degree of evacuation of the tube and the relation of its parts being such that for voltages materially above ionization voltage the current is governed or limited by the electric field of the electrons in said tube substantially unaffected by positive ionization, and a third electrode in said tube by which an auxiliary controlling electromotive force may be superposed to modify the effect of said electric field and control said current in a stable and reproducible manner.

22. The method of controlling an electric current in one circuit by an electromotive force in another circuit which consists in causing said current at voltages materially above ionization voltages to pass as a discharge across a vacuous space between an electron emitting cathode and an anode, maintaining a high vacuum in said space, governing or limiting the current by a space charge effect in said space substantially unaffected by positive ionization, and superimposing the effect of said electromotive force on said space charge effect to control said current in a stable and reproducible manner.

23. A discharge device comprising a tube and electrodes therein, one of which is a cathode, the discharge passing in the main directly between electrodes, the degree of evacuation and the relation of the parts of the device being such that the device is capable of being so operated below saturation and at voltages materially higher than the ionization voltages, that the slope or location of the logarithmic line of current with respect to voltage is not changed by changes in the temperature of the cathode.

24. A discharge device comprising a tube and electrodes therein, one of which is a cathode adapted to be heated and to emit electrons thereby, the discharge passing directly between electrodes, the degree of evacuation and the relation of the parts of the device being such that the device is capable of being so operated below saturation and at voltages materially higher than the ionization voltage, that the plot of the current against the voltage is not changed with changes in the temperature of the cathode.

25. A discharge device comprising a sealed off envelope having therein a cathode adapted to be heated independently of the discharge and to deliver electrons thereby, and an anode, the inner wall of the envelope and the electrodes being sufficiently free of occluded gas, and the free gas within the envelope being such, so that the finished device is capable of sustained operation below saturation in a stable and reproducible manner with currents of more than one milliampere at voltages materially higher than the ionization voltages and with the energy of the discharge delivered mainly at an electrode or electrodes.

26. A discharge device comprising a sealed off envelope and electrodes therein, the envelope being shaped and the electrodes located so that the energy of the discharge is delivered mainly upon one or more of the electrodes, the inner wall of the envelope and electrodes being so free from occluded gas and the pressure in the tube being sufficiently low, with respect to the spacing of the electrodes and the energy of the discharge, so that the device is capable of passing a sustained discharge of one tenth of a milliampere at forty volts, without developing any substantial positive ionization effects.

27. A discharge device comprising a sealed off envelope and electrodes therein, one of which is a cathode adapted to be heated independently of the discharge and to emit electrons thereby, the inner wall of the envelope and the electrodes being so free from occluded gas that the device is capable of passing a sustained discharge of one milliampere at fifty volts with the energy of the discharge delivered mainly at an electrode or at electrodes without liberating any substantial amount of gas into the space within the envelope.

28. A discharge device comprising a sealed-off envelope and electrodes therein, one of which is a cathode adapted to be heated independently of the discharge and to emit electrons thereby, the inner wall of the envelope and the electrodes being so free from occluded gas that the device is capable of passing a sustained discharge of two milliamperes at one hundred volts with the energy of the discharge delivered mainly at an electrode or at electrodes without liberating any substantial amount of gas into the space within the envelope.

29. An electrical discharge device comprising a gas-tight envelope, a cathode adapted to be heated to incandescence, an anode from which substantially no ionizable gas can be evolved at operating voltages up to forty volts with currents up to one-tenth milliampere, the envelope so shaped and the electrodes so positioned as to substantially avoid secondary electron emission from the wall of the envelope, the space in said en-

velope being evacuated to a pressure not in substantial excess of a few hundred thousandths of a millimeter of mercury.

30. In the process of producing a discharge device, removing the occluded gas from the interior surface of the envelope thereof and from the electrodes to such an extent that the finished sealed-off device will operate, without liberating any substantial amount of gas into the space within the envelope, at voltages materially above the ionization voltage with currents greater than one milliampere and with substantially all the energy of the discharge delivered to an anode or anodes.

31. In the process of producing a hot cathode discharge device, treating the interior surface of the envelope and the operating parts to liberate therefrom occluded gas, and removing from the envelope gas liberated by said treatment and free gas originally contained therein, continuing these operations until the occluded and original free gas is so thoroughly removed as to enable the finished sealed-off device to operate below saturation in a stable and reproducible manner at a voltage above fifty volts and with a current greater than one milliampere and with the energy of the discharge delivered mainly at one or more anodes.

32. The process of producing a discharge device which consists in treating the envelope and enclosed parts thereof to liberate gas therefrom and removing from the envelope gas which is thereby liberated and free gas originally contained in the envelope, the treatment being sufficiently powerful and being sufficiently prolonged and the removal of the liberated and original free gas from the envelope being sufficiently thorough, so that the finished sealed-off device is capable of sustained operation substantially without positive ionization at voltages as high as one hundred volts with currents as great as one milliampere and with substantially the entire energy of the discharge delivered upon the anode or anodes of the device.

In witness whereof, I have hereunto set my hand this 15th day of October 1913.

IRVING LANGMUIR.

PETITION

To the Honorable Commissioner of Patents:

Your petitioner Irving Langmuir

a citizen of the United States, residing at Schenectady

in the County of Schenectady State of New York

whose Post Office address is C/o General Electric Co., Schenectady, N. Y.,

prays that Letters Patent may be granted him for the improvement in

Electron Discharge Apparatus and Method of Preparation (D-19806)

set forth in the accompanying specification.

And he further prays that you will recognize Mr. Albert G. Davis, of Schenectady, New York, as his attorney, with full power of substitution and revocation, to prosecute this application, to make alterations and amendments therein, to receive the patent, and to transact all business in the Patent Office connected therewith.

Irving Langmuir

[illegible]

TO ALL WHOM IT MAY CONCERN:

BE IT KNOWN, that I, IRVING LANGMUIR, a citizen of the United States, residing at Schenectady, in the County of Schenectady, State of New York, have invented certain new and useful improvements in ELECTRON-DISCHARGE APPARATUS AND METHOD OF PREPARATION, of which the following is a specification.

The present invention relates to electrical devices operating with a pure electron discharge and comprises a novel cathode material and the method of its preparation.

In a previous application, Serial No. 795,610, filed October 16, 1913, I have described and claimed a new type of electrical discharge apparatus comprising an envelope containing electrodes one of which emits electrons and being so highly evacuated that positive ionization is negligible. Some of the characteristics of this "pure electron discharge" are absence of conductivity in the space between independent unheated electrodes, a variation of the current over a certain range with the 3/2 power of the voltage, the absence of blue glow in the space, the absence of gas fluorescence and the lack of cathodic disintegration.

Various refractory materials, platinum, carbon, tungsten and molybdenum, have been used as cathode materials and it has been found that the emissivity of electrons of these various materials while differing to some degree ~~are all~~ is of the same order of magnitude.

I have discovered that the electron emissivity of pure thorium is of an entirely different order of magnitude than the emissivity of refractory materials heretofore used in electron discharge devices. It is not necessary that the electrode should consist entirely of thorium. When, for example, a thorium compound, such as the oxid~~e~~, has been added during the process of production to one of the highly refractory metals, for example, tungsten, and the metal subjected to a preliminary heat treatment in a high vacuum, the electron emission in a high vacuum is enormously increased. This increased emissivity is not due to the presence of thorium oxid~~e~~ in the manner of the Wehnelt cathode for various reasons hereinafter explained, but according to all indications is a property of metallic thorium on the surface of the cathode.

Apparatus suitable for preparing and utilizing a thoriated cathode in an electron discharge apparatus is somewhat diagrammatically shown in the accompanying drawings, in which Fig. 1 shows a simple type of apparatus in which the anode consists of a film of refractory metal on the inside wall of the envelop~~e~~ produced by vaporizing a refractory metal at high temperature; Fig. 2 is a device operable as a rectifier having a thoriated cathode and plate-shaped anodes; and Fig. 3 illustrates a modification in which active thorium material may be transferred to the cathode from an independent thoriated conductor.

The device shown in Fig. 1 comprising an envelope 1 consisting of glass, quartz or the like provided with two filamentary conductors 2, 3, of highly refractory metal, such for example as tungsten, at least one of which, say filament 2, is thoriated. They are connected to leading-in wires 4, 5, sealed into a stem 6 in the well-known manner. The envelope is connected to a vacuum system by a tube 7, containing a trap 8 which may be surrounded by a freezing bath, such as liquid air, contained in a Dewar flask 9 or even an ice and salt mixture. It is the function of the freezing bath to prevent mercury, or other vapors, from the vacuum pumps from reaching the envelop~~e~~ 1.

The preliminary evacuation of the envelop~~e~~ is carried out by the usual methods of producing high vacuum, which includes baking out the envelop~~e~~ to remove water vapor. The final stages of the evacuation is preferably but not necessarily carried out by a Gaede molectlar pump to the highest possible vacuum obtainable by this means, - that is, to about .001 micron. While the apparatus is still on the pump the filaments 2, 3, are heated to a temperature of about 2900° K. (absolute) for a short time and the envelop~~e~~ 1 is baked out in an oven at a temperature of about 360 to 450° K. The apparatus may then be sealed from the vacuum system at the contraction 10. It is then preferably immersed in liquid air and both filaments 2,3 aged by heating for about 1/2 hour to a temperature of 2400 to 2500° K. One of the filaments, for example, filament 3, is then incandesced by a passage of current to a temperature of about 3000° K. which causes rapid vaporization of the metal, thereby producing a gas-free conducting deposit or coating 11 which has been shown on the inner surface of the envelop~~e~~. Conductors 12, 13 sealed into the envelop~~e~~ make contact with this coating and enable it to be used as an anode for an electrical discharge. A device having a gas-free film anode and the method of its preparation has been described and claimed by me in a co-pending application, Serial No. 843,569, filed June 6, 1914. The method of producing high vacuum by vaporizing tungsten is claimed by me in a co-pending application, Serial No. 838,768, filed May 15, 1914. Pressures much below .001 micron of mercury may be attained thereby. The cathode conductor 2 is prepared by introducing a thorium compound, such as the nitrate of thorium to the oxid~~e~~ of

Per B

B

the refractory metal before reduction, or by adding either ~~the~~ thorium nitrate or thoria to the metal powder after reduction but before consolidation of the metal by sintering and mechanical working to the solid metal state has taken place as described, for example, with reference to thoriated tungsten in U. S. patent No. 1,082,933. The proportion of thoria in the unsintered metal usually varies from about 1/2% to 10% but in some cases may be even greater. The proportion of thorium compound in the cathode within the above limits makes little difference in the maximum electron emission that may be obtained under the best conditions but with a greater proportion of thorium compound the desired active condition of the filament may be reached and maintained with greater ease than with a lesser amount.

The thoriated cathode 2 is now heated to about 2900° K. for about one minute. The treatment of the filament at a temperature of 2900° has no marked effect on the subsequent electron emission of the cathode when at lower temperature but appears to be desirable for purifying the surface of the cathode. The cathode is then incandesced within the range of about 2000° to 2400° K. and by this temperature treatment some change is produced in the cathode which enormously increases its electron-emitting property under the condition described. The greatest activity is obtained between about 2200° to 2300° K. and the treatment at this temperature is usually continued for about one minute, but even outside of this range a marked change is produced. Apparently a concentration of metallic thorium or of some other oxidisable thorium material takes place on the surface of the filament. The filament 2 may now be used as a cathode at a temperature below this forming temperature.

With a filament thus prepared I have obtained at a temperature of about 1300° to 1380° K. substantially the same electron emission per sq. cm. as with a pure tungsten filament at about 2000° K., that is, about three milliamperes per sq. cm. Preferably a thoriated cathode is operated around 1700° to 1800° K., at which temperatures its life is indefinitely long.

Subsequently heating the filament to a higher temperature, for example, to 2800° K., causes some change, apparently a distillation of the film of thorium from the surface, as the electron emitting power of the cathode falls to the same order of magnitude as pure metal. When the cathode after being thus heated is re-subjected to a temperature of 2200° to 2300° K., the active condition is restored.

A similar heat treatment of pure tungsten has no effect on its electron emissivity at incandescence. The active thorium material may be transferred by distillation to an adjacent surface. For example, if the filament 3 consisting of pure tungsten has not been completely destroyed during the preparation of the apparatus, the heating of the cathode to a temperature above 2300° after the preparation of the surface film results in the distillation of some of the thorium material to conductor 3 so that when the conductor 3 is used as a cathode with respect to the anode 11, it is found that its electron emission has been greatly increased.

One of the most striking proofs that the active surface film is not due to the effect of the thoria as in the Wehnelt cathode is furnished by the effect of a minute trace of oxygen on the behavior of the cathode. If in some manner a trace of oxygen is admitted, the electron emission immediately falls as low or even lower than the low value observed when a cathode of pure tungsten is slightly oxidized. In other words, the electron emission becomes very much lower than that of the unoxidized metal. When subsequent to oxidation a trace of hydrocarbon vapor is admitted, the electron emission suddenly rises as though reduction were taking place. If the carbon is in excess, the electron emissivity immediately drops to a low value as though a carbide were formed with the excess of carbon. (3) B'

Insert B'

Cathodes containing only a small amount of thorium compound are deleteriously affected by disintegration of the surface produced by positive ion bombardment and in this respect may be extremely sensitive. In this case, it is necessary when using voltages high enough to cause ionization of residual gases to carry the vacuum far beyond the point at which a disruptive discharge no longer takes place, which ordinarily is about 1/10 of a micron of mercury pressure. The Wehnelt or oxide cathode apparently depends on positive ionization for its activity. At any rate its emissivity is increased by an increase in positive ionization. When large amounts of thorium are present in my improved cathode, it is not so sensitive to positive ion bombardment and it is possible to obtain to a large extent the advantages of a thoriated cathode even in the presence of pressures of gas up to atmospheric pressure.

Another proof that the high electron emission is due to a skin of thorium is the fact that metallic thorium itself, particularly when free from surface oxidation, exhibits a very high electron emissivity for a given temperature as compared with tungsten. Difficulties are encountered with the use of metallic thorium as cathode material due to its relatively low melting point and its susceptibility to oxidation ~~oxidation~~.

Rec B

At 2000° to 2300° K., the active thorium is slowly diffusing to the surface from the interior of the metal.

As the temperature is raised a point is reached where the distillation of thorium from the surface exceeds the rate at which the metal diffuses to the surfaces. It is possible, however, to operate a refractory thoriated cathode at a temperature between 2000° and 2200° K. for a long time without destroying its high electron emission, but operation at a higher temperature is not advisable. A sufficiently great electron emission can be secured through the indicated temperature range with an accompanying saving of energy necessary for heating the cathode.

The apparatus shown in Fig. 2 does not differ essentially from the apparatus shown in Fig. 1, plate-shaped anodes 15, 16 consisting of a highly refractory metal such as tungsten being used instead of the film anode of vaporized metal used in the apparatus shown in Fig. 1. The envelope 17 is baked out and evacuated as already described in connection with Fig. 1. The ionizable gas should be removed from the anodes during the final stages of the exhaust after the pressure has been reduced below about 1/10 of a micron of mercury by subjecting the anodes to an electron discharge from the cathode 18 whereby ionizable gas is evolved, as disclosed in my co-pending application, Serial No. 795,610 of October 16, 1913. This gas should be removed as fast as liberated and the discharge voltage progressively increased, care being taken not to materially exceed the voltage at which blue glow takes place so as to avoid injury to the cathode. The final stage of the evacuation is produced by vaporizing a tungsten conductor in a side chamber (not shown in the drawing), thereby producing the very high vacuum necessary for the operation of the thoriated cathode. The anodes 15, 16 may be both connected to one terminal of a secondary of the transformer

19, by conductors 20, 21, the cathode being connected to the other terminal by conductor 22, including a load circuit 23. The cathode 18 has been merely indicated by dotted lines as being a V-shaped filament supported by terminal wires 24, 25, and maintained taut at its bight by a spring 26, but it is to be understood that it may have any convenient form. Thorium compound, for example, the oxide, is introduced during the process of manufacture as already described. The apparatus here shown is suitable for the rectification of alternating current when the cathode is maintained at incandescence by a battery 27, preferably at a temperature of 1700 to 1800° K.

It is not absolutely necessary that the thorium should be introduced into the body of the metal during the process of manufacture. As shown in Fig. 3 a cathode 28 located opposite an anode 29 is provided with a film of active thorium material vaporized from the coiled filamentary cathode 30 heated by a battery 31. The cathode 30 may consist either of a thoriated cathode prepared as already described, or of metallic thorium. The enclosing envelope has not been shown, but it is to be understood that these parts are to be operated in the high vacuum already indicated as being desirable. When the coil 30 consists of thoriated wire it is first rendered active by heat treatment at a temperature of 2200° to 2300° K., as already described, and is then heated to a temperature of about 2900° K. to distill off active material, some of which is condensed on the cathode 28. When the coil 30 consists of metallic thorium, it should be heated to a temperature near its melting point to distill some of the thorium over on to the surface of the cathode 28.

As positive ionization is very much decreased at low voltages, it is permissible to have present an inert gas at a pressure of say .01 micron when the voltage impressed between the cathode and anode does not arise above the ionizing potential of the gas. Advantage can be taken of this fact to use an electron discharge device containing a thoriated cathode as a voltage sensitive cut-out device. Below the voltage at which disintegration of the surface begins, a device such as shown in Fig. 1 may be used to pass a current of about 3/10 of an ampere per sq. cm. when the cathode is at a temperature of about 1700° to 1800° K. When the voltage rises above the critical value, the current immediately drops to a very small value, thus practically interrupting the circuit. The cathode may be restored when the voltage has fallen by again heating it to about 2200° to 2350° K.

What I claim as new and desire to secure by Letters Patent of the United States, is:

1. In an electrical discharge device, an electrode comprising in part at least oxidisable thorium material, said electrode having at a temperature of about 1300 to 1380° absolute an electron emission substantially equal to that of tungsten at about 2000° absolute.

Ⓑ

2. In an electrical discharge device, an electrode comprising in part at least oxidisable thorium and having when at incandescence in a vacuum so highly attenuated that positive ionization is substantially absent, an electron emission materially greater per unit of surface than tungsten at the same temperature.

3. A cathode for electron-discharge apparatus consisting largely of a highly refractory metal and a surface layer of material having an electron emissivity at a given temperature materially greater per unit surface than said refractory metal independently of and in the absence of positive ionization.

4. In a device operating by pure electron discharge independent of positive ionization, a conductor comprising a refractory metal and a surface film of thorium material vaporizable at a temperature above about 2300° ~~C.~~ K. and having a greater electron emission when at incandescence in a non-striking vacuum than said refractory metal.

Ⓑ

5. In an electrical discharge device, an electrode comprising metallic tungsten and a surface film of thorium material vaporizable at a temperature above about 2300° ~~C.~~ K. removable from said surface by positive ionization

Ⓑ

and having an electron emission per unit surface many times greater than pure tungsten at the same temperature.

6. In an electrical discharge device, an electrode comprising metallic tungsten and thoria said electrode having been subjected to a temperature of about 2200 to 2350° K. and having an electron emission a thousand times as great per unit of surface as tungsten in a vacuum too high to permit of positive ionization.

7. In an electrical discharge device, a cathode comprising metallic tungsten and thoria, said electrode having received a heat treatment at about 2000 to 2350° K. and having an electron emission when at incandescence at a given temperature of a higher order of magnitude than pure tungsten at the same temperature.

8. The process of preparing an electrode comprising a refractory metal and thoria for use in a pure electron discharge apparatus which consists in heating said electrode to a temperature adjacent the melting point of said refractory metal and then heating to a temperature of about 2200 to 2300° ~~K~~ absolute.

Per B

9. The process which consists in heating a conductor comprising tungsten and thoria to a temperature of about 2800 to 2900° absolute ~~K~~. and then lowering the temperature to about 2200 to 2300° absolute ~~K~~. holding said temperature for a short interval and finally operating said conductor as cathode in a non-striking vacuum at a temperature below 2000° absolute ~~K~~.

Div. 16, Room 109. :

Honorable Commissioner of Patents,

Sir:-

In response to the Office Action of October 3, 1914, please amend the above-entitled case as follows:-

✓ Page 3, line 6, change "stages" to - stage -

✓ Page 6, after the sentence ending with the word "carbon", line 6, add the following:

- When a volatile alkali metal, such as potassium, is used as a reducing agent for a thoriated cathode, the high emissivity of the thoriated cathode is quickly and easily secured and maintained. The potassium may be distilled into the main envelope or introduced in a thin walled exhausted glass capsule which is broken after the necessary vacuum has been produced in the envelope.. The advantages of an alkali metal, such as potassium, as a reducer are (1) a vapor pressure so low that objectionable positive ionization of its own vapor is negligible, (2) the strong reducing action maintains the thorium reduced in spite of traces of water vapor which may be liberated from the glass (3) the oxidation products of the potassium have no perceptible vapor pressure, (4) an excess of potassium does not combine with the filament and hence does no harm. Potassium vapor does not produce an increase of

Per B

Q

electron emission of a pure tungsten cathode.

Add the following claim:

~~10. A cathode for electron discharge apparatus consisting largely of tungsten and containing thorium having an electron emissivity at a given temperature materially greater per unit surface than tungsten at the same temperature independently of and in the absence of positive ionization.~~

DEPARTMENT OF THE INTERIOR
UNITED STATES PATENT OFFICE
WASHINGTON Nov. 22, 1915.

Irving Langmuir, Assor.

Sir: Your APPLICATION for a patent for an IMPROVEMENT in Electron Discharge Apparatus and Method of Preparation, filed July 15, 1914 , has been examined and ALLOWED.

The final fee, TWENTY DOLLARS, must be paid not later than SIX MONTHS from the date of this present notice of allowance. If the final fee be not paid within that period, the patent on this application will be withheld, unless renewed with an additional fee of $15, under the provisions of Section 4897, Revised Statutes.

The office delivers patents upon the day of their date, and on which their term begins to run. The printing, photolithographing, and engrossing of the several patent parts, preparatory to final signing and sealing, will require about four weeks, and such work will not be undertaken until after payment of the necessary fee.

When you send the final fee you will also send, DISTINCTLY AND PLAINLY WRITTEN, the name of the INVENTOR, TITLE OF INVENTION, AND SERIAL NUMBER AS ABOVE GIVEN, DATE OF ALLOWANCE (which is the date of this circular), DATE OF FILING, and, if assigned, the NAMES OF THE ASSIGNEES.

If you desire to have the patent issue to ASSIGNEES, an assignment containing a REQUEST to that effect, together with the FEE for recording the same, must be filed in this office on or before the date of payment of final fee.

After issue of the patent uncertified copies of the drawings and specifications may be purchased at the price of FIVE CENTS EACH. The money should accompany the order. Postage stamps will not be received.

Final fees will NOT be received from other than the applicant, his assignee or attorney, or a party in interest as shown by the records of the Patent Office.

Respectfully,

Thomas Ewing
Commissioner of Patents.

Albert G. Davis,
% General Electric Company,
Schenectady, N. Y.

UNITED STATES PATENT OFFICE.

IRVING LANGMUIR, OF SCHENECTADY, NEW YORK, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

ELECTRON-DISCHARGE APPARATUS AND METHOD OF PREPARATION.

1,244,216. Specification of Letters Patent. Patented Oct. 23, 1917.

Application filed July 15, 1914, Serial No. 851,095. Renewed June 25, 1917. Serial No. 176,936.

To all whom it may concern:

Be it known that I, Irving Langmuir, a citizen of the United States, residing at Schenectady, in the county of Schenectady, State of New York, have invented certain new and useful Improvements in Electron-Discharge Apparatus and Methods of Preparation, of which the following is a specification.

The present invention relates to electrical devices operating with a pure electron discharge and comprises a novel cathode material and the method of its preparation.

In a previous application, Serial No. 795,610, filed October 16, 1913, I have described and claimed a new type of electrical discharge apparatus comprising an envelop containing electrodes one of which emits electrons and being so highly evacuated that positive ionization is negligible. Some of the characteristics of this "pure electron discharge" are absence of conductivity in the space between independent unheated electrodes, a variation of the current over a certain range with the 3/2 power of the voltage, the absence of blue glow in the space, the absence of gas fluorescence and the lack of cathodic disintegration.

Various refractory materials, platinum, carbon, tungsten and molybdenum, have been used as cathode materials and it has been found that the emissivity of electrons of these various materials while differing to some degree is of the same order of magnitude.

I have discovered that the electron emissivity of pure thorium is of an entirely different order of magnitude than the emissivity of refractory materials heretofore used in electron discharge devices. It is not necessary that the electrode should consist entirely of thorium. When, for example, a thorium compound, such as the oxid, has been added during the process of production to one of the highly refractory metals, for example, tungsten, and the metal subjected to a preliminary heat treatment in a high vacuum, the electron emission in a high vacuum is enormously increased. This increased emissivity is not due to the presence of thorium oxid in the manner of the Wehnelt cathode for various reasons hereinafter explained, but according to all indications is a property of metallic thorium on the surface of the cathode.

Apparatus suitable for preparing and utilizing a thoriated cathode in an electron discharge apparatus is somewhat diagrammatically shown in the accompanying drawings, in which Figure 1 shows a simple type of apparatus in which the anode consists of a film of refractory metal on the inside wall of the envelop produced by vaporizing a refractory metal at high temperature; Fig. 2 is a device operable as a rectifier having a thoriated cathode and plate-shaped anodes; and Fig. 3 illustrates a modification in which active thorium material may be transferred to the cathode from an independent thoriated conductor.

The device shown in Fig. 1 comprising an envelop 1 consisting of glass, quartz or the like provided with two filamentary conductors 2, 3, of highly refractory metal, such for example as tungsten, at least one of which, say filament 2, is thoriated. They are connected to leading-in wires 4, 5, sealed into a stem 6 in the well-known manner. The envelop is connected to a vacuum system by a tube 7, containing a trap 8 which may be surrounded by a freezing bath, such as liquid air, contained in a Dewar flask 9 or even an ice and salt mixture. It is the function of the freezing bath to prevent mercury, or other vapors, from the vacuum pumps from reaching the envelop 1.

The preliminary evacuation of the envelop is carried out by the usual methods of producing high vacuum, which includes baking out the envelop to remove water vapor. The final stage of the evacuation is preferably but not necessarily carried out by a Gaede molecular pump to the highest possible vacuum obtainable by this means,—that is, to about .001 micron. While the apparatus is still on the pump the filaments 2, 3, are heated to a temperature of about 2900° K. (absolute) for a short time and the envelop 1 is baked out in an oven at a temperature of about 360 to 450° K. The apparatus may then be sealed from the vacuum system at the contraction 10. It is then preferably immersed in liquid air and both filaments 2, 3 aged by heating for about ½ hour to a temperature of 2400 to 2500° K. One of the filaments, for example, filament

3, is then incandesced by a passage of current to a temperature of about 3000° K. which causes rapid vaporization of the metal, thereby producing a gas-free conducting deposit or coating 11 which has been shown on the inner surface of the envelop. Conductors 12, 13 sealed into the envelop make contact with this coating and enable it to be used as an anode for an electrical discharge. A device having a gas-free film anode and the method of its preparation has been described and claimed by me in a copending application, Serial No. 848,569, filed June 8, 1914. The method of producing high vacua by vaporizing tungsten is claimed by me in a co-pending application, Serial No. 838,768, filed May 15, 1914. Pressures much below .001 micron of mercury may be attained thereby. The cathode conductor 2 is prepared by introducing a thorium compound, such as the nitrate of thorium to the oxid of the refractory metal before reduction, or by adding either thorium nitrate or thoria to the metal powder after reduction but before consolidation of the metal by sintering and mechanical working to the solid metal state has taken place as described, for example, with reference to thoriated tungsten in U. S. Patent No. 1,082,933. The proportion of thoria in the unsintered metal usually varies from about ½ to 10% but in some cases may be even greater. The proportion of thorium compound in the cathode within the above limits makes little difference in the maximum electron emission that may be obtained under the best conditions but with a greater proportion of thorium compound the desired active condition of the filament may be reached and maintained with greater ease than with a lesser amount.

The thoriated cathode 2 is now heated to about 2900° K. for about one minute. The treatment of the filament at a temperature of 2900° has no marked effect on the subsequent electron emission of the cathode when at lower temperature but appears to be desirable for purifying the surface of the cathode. The cathode is then incandesced within the range of about 2000° to 2200° K. and by this temperature treatment some change is produced in the cathode which enormously increases its electron-emitting property under the condition described. The greatest activity is obtained between about 2200° to 2300° K. and the treatment at this temperature is usually continued for about one minute, but even outside of this range a marked change is produced. Apparently a concentration of metallic thorium or of some other oxidizable thorium material takes place on the surface of the filament. The filament 2 may now be used as a cathode at a temperature below this forming temperature.

With a filament thus prepared I have obtained at a temperature of about 1300° to 1380° K. substantially the same electron emission per sq. cm. as with a pure tungsten filament at about 2000° K., that is, about three milliamperes per sq. cm. Preferably a thoriated cathode is operated around 1700° to 1800° K., at which temperatures its life is indefinitely long.

Subsequently heating the filament to a higher temperature, for example, to 2800° K., causes some change, apparently a distillation of the film of thorium from the surface, as the electron emitting power of the cathode falls to the same order of magnitude as pure metal. When the cathode after being thus heated is re-subjected to a temperature of 2200° to 2300° K., the active condition is restored.

A similar heat treatment of pure tungsten has no effect on its electron emissivity at incandescence. The active thorium material may be transferred by distillation to an adjacent surface. For example, if the filament 3 consisting of pure tungsten has not been completely destroyed during the preparation of the apparatus, the heating of the cathode to a temperature above 2300° after the preparation of the surface film results in the distillation of some of the thorium material to conductor 3 so that when the conductor 3 is used as a cathode with respect to the anode 11, it is found that its electron emission has been greatly increased.

One of the most striking proofs that the active surface film is not due to the effect of the thoria as in the Wehnelt cathode is furnished by the effect of a minute trace of oxygen on the behavior of the cathode. If in some manner a trace of oxygen is admitted, the electron emission immediately falls as low or even lower than the low value observed when a cathode of pure tungsten is slightly oxidized. In other words, the electron emission becomes very much lower than that of the unoxidized metal. When subsequent to oxidation a trace of hydrocarbon vapor is admitted, the electron emission suddenly rises as though reduction were taking place. If the carbon is in excess, the electron emissivity immediately drops to a low value as though a carbid were formed with the excess of carbon. In an application Serial No. 58,377 filed by me on October 28, 1915, I have more fully described and also claimed a thoriated cathode device containing reducing material.

Cathodes containing only a small amount of thorium compound are deleteriously affected by disintegration of the surface produced by positive ion bombardment and in this respect may be extremely sensitive. In this case, it is necessary when using voltages high enough to cause ionization of residual gases to carry the vacuum far beyond the point at which a disruptive discharge no longer takes place, which ordinarily is about $\frac{1}{10}$ of a micron of mercury pressure. The Wehnelt or oxid cathode apparently depends on positive ionization for its activity. At any rate its emissivity is increased by an increase in positive ionization. When large amounts of thorium are present in my improved cathode, it is not so sensitive to positive ion bombardment and it is possible to obtain to a large extent the advantages of a thoriated cathode even in the presence of pressures of gas up to atmospheric pressure.

Another proof that the high electron emission is due to a skin of thorium is the fact that metallic thorium itself, particularly when free from surface oxidation, exhibits a very high electron emissivity for a given temperature as compared with tungsten. Difficulties are encountered with the use of metallic thorium as cathode material due to its relatively low melting point and its susceptibility to oxidation.

At 2000° to 2300° K., the active thorium is slowly diffusing to the surface from the interior of the metal. As the temperature is raised a point is reached where the distillation of thorium from the surface exceeds the rate at which the metal diffuses to the surfaces. It is possible, however, to operate a refractory thoriated cathode at a temperature between 2000° and 2200° K. for a long time without destroying its high electron emission, but operation at a higher temperature is not advisable. A sufficiently great electron emission can be secured through the indicated temperature range with an accompanying saving of energy necessary for heating the cathode.

The apparatus shown in Fig. 2 does not differ essentially from the apparatus shown in Fig. 1, plate-shaped anodes 15, 16 consisting of a highly refractory metal such as tungsten being used instead of the film anode of vaporized metal used in the apparatus shown in Fig. 1. The envelop 17 is baked out and evacuated as already described in connection with Fig. 1. The ionizable gas should be removed from the anodes during the final stages of the exhaust after the pressure has been reduced below about $\frac{1}{10}$ of a micron of mercury by subjecting the anodes to an electron discharge from the cathode 18 whereby ionizable gas is evolved, as disclosed in my co-pending application, Serial No. 795,610 of October 16, 1913. This gas should be removed as fast as liberated and the discharge voltage progressively increased, care being taken not to materially exceed the voltage at which blue glow takes place so as to avoid injury to the cathode. The final stage of the evacuation is produced by vaporizing a tungsten conductor in a side chamber (not shown in the drawing), thereby producing the very high vacuum necessary for the operation of the thoriated cathode. The anodes 15, 16 may be both connected to one terminal of a secondary of the transformer 19, by conductors 20, 21, the cathode being connected to the other terminal by conductor 22, including a load circuit 23. The cathode 18 has been merely indicated by dotted lines as being a V-shaped filament supported by terminal wires 24, 25, and maintained taut at its bight by a spring 26, but it is to be understood that it may have any convenient form. Thorium compound, for example, the oxid, is introduced during the process of manufacture as already described. The apparatus here shown is suitable for the rectification of alternating current when the cathode is maintained at incandescence by a battery 27, preferably at a temperature of 1700 to 1800° K.

It is not absolutely necessary that the thorium should be introduced into the body of the metal during the process of manufacture. As shown in Fig. 3 a cathode 28 located opposite an anode 29 is provided with a film of active thorium material vaporized from the coiled filamentary cathode 30 heated by a battery 31. The cathode 30 may consist either of a thoriated cathode prepared as already described, or of metallic thorium. The inclosing envelop has not been shown, but it is to be understood that these parts are to be operated in the high vacuum already indicated as being desirable. When the coil 30 consists of thoriated wire it is first rendered active by heat treatment at a temperature of 2200° to 2300° K., as already described, and is then heated to a temperature of about 2900° K. to distil off active material, some of which is condensed on the cathode 28. When the coil 30 consists of metallic thorium, it should be heated to a temperature near its melting point to distil some of the thorium over on to the surface of the cathode 28.

As positive ionization is very much decreased at low voltages, it is permissible to have present an inert gas at a pressure of say .01 micron when the voltage impressed between the cathode and anode does not arise above the ionizing potential of the gas. Advantage can be taken of this fact to use an electron discharge device containing a thoriated cathode as a voltage sensitive cut-out device. Below the voltage at which disintegration of the surface begins, a device such as shown in Fig. 1 may be used to pass a current of about $\frac{1}{10}$ of an ampere per sq. cm. when the cathode is at a temperature of about 1700° to 1800° K. When the voltage rises above the critical value, the current immediately drops to a very small value, thus practically interrupting the circuit. The cathode may be restored when the voltage has fallen by again heating it to about 2200° to 2300° K.

What I claim as new and desire to secure by Letters Patent of the United States, is:—

1. In an electrical discharge device, an electrode comprising in part at least oxidizable thorium material, said electrode having at a temperature of about 1800 to 1380° absolute an electron emission substantially equal to that of tungsten at about 2000° absolute.

2. In an electrical discharge device, an electrode comprising in part at least oxidizable thorium and having when at incandescence in a vacuum so highly attenuated that positive ionization is substantially absent, an electron emission materially greater per unit of surface than tungsten at the same temperature.

3. A cathode for electron-discharge apparatus consisting largely of a highly refractory metal and a surface layer of material having an electron emissivity at a given temperature materially greater per unit surface than said refractory metal independently of and in the absence of positive ionization.

4. In a device operating by pure electron discharge independent of positive ionization, a conductor comprising a refractory metal and a surface film of thorium material vaporizable at a temperature above about 2300° K. and having a greater electron emission when at incandescence in a non-striking vacuum than said refractory metal.

5. In an electrical discharge device, an electrode comprising metallic tungsten and a surface film of thorium material vaporizable at a temperature above about 2300° K. removable from said surface by positive ionization and having an electron emission per unit surface many times greater than pure tungsten at the same temperature.

6. In an electrical discharge device, an electrode comprising metallic tungsten and thoria said electrode having been subjected to a temperature of about 2200 to 2350° K. and having an electron emission a thousand times as great per unit of surface as tungsten in a vacuum too high to permit of positive ionization.

7. In an electrical discharge device, a cathode comprising metallic tungsten and thoria, said electrode having received a heat treatment at about 2000 to 2350° K. and having an electron emission when at incandescence at a given temperature of a higher order of magnitude than pure tungsten at the same temperature.

8. The process of preparing an electrode comprising a refractory metal and thoria for use in a pure electron discharge apparatus which consists in heating said electrode to a temperature adjacent the melting point of said refractory metal and then heating to a temperature of about 2200 to 2300° absolute.

9. The process which consists in heating a conductor comprising tungsten and thoria to a temperature of about 2800 to 2900° absolute and then lowering the temperature to about 2200 to 2300° absolute holding said temperature for a short interval and finally operating said conductor as cathode in a non-striking vacuum at a temperature below 2000° absolute.

10. A cathode for electron discharge apparatus consisting largely of tungsten and containing thorium, said cathode having an electron emissivity, independently of and in the absence of positive ionization, at a given temperature materially greater per unit surface than tungsten at the same temperature.

11. In an incandescent cathode device, an electrode comprising a highly refractory metal and containing oxidizable thorium material, said electrode having an electron emissivity per unit surface many times greater than said refractory metal alone at the same temperature, the electron emissivity of said cathode being lowered by the presence of oxygen and by positive ionization.

In witness whereof, I have hereunto set my hand this 14th day of July, 1914.

(No. of Claims Allowed 8) Title as Allowed Electron Discharge Apparatus and Method of Operating the Same (Cl. 250-27)

PETITION

To the Honorable Commissioner of Patents:

our petitioner, Irving Langmuir,

a citizen of the United States, residing at Schenectady

in the County of Schenectady, State of New York

whose Post Office address is c/o General Electric Company, Schenectady, N.Y.

prays that Letters Patent may be granted him for the improvement in

Electron Discharge Apparatus and Method of Operating the Same

D-20,387

set forth in the accompanying specification.

And he further prays that you will recognize Mr. Albert G. Davis, of Schenectady, New York, as his attorney, with full power of substitution and revocation, to prosecute this application, to make alterations and amendments therein, to receive the patent, and to transact all business in the Patent Office connected therewith.

Irving Langmuir

TO ALL WHOM IT MAY CONCERN:

BE IT KNOWN, that I, Irving Langmuir, a citizen of the United States, residing at Schenectady, in the County of Schenectady, State of New York, have invented certain new and useful Improvements in Electron Discharge Apparatus and Methods of Operating the Same, of which the following is a specification.

The present invention relates to electrical devices having an electrode consisting at least in part of thorium and having at a given temperature an electron emission per unit surface materially greater than the emission of a refractory metal such as tungsten at the same temperature independently of and in the absence of positive ionization. These devices are described and claimed in a copending application, Serial No. 861,095, of July 15,1914, renewed on June 25, 1917, as application Serial No. 176926 to which the present application is closely related.

Per B.

In the preparation of these devices great care must be exercised to remove the last traces of oxygenous gases, particularly water vapor, and precautions must be observed not to evolve water vapor from the bulb walls during the operation of the device.

In accordance with my present invention, I have improved the above described device and rendered easier the preparation of the same by providing in the envelope a quantity of a vaporizable reagent of low vapor pressure capable of preventing the oxidation of thorium. I prefer to use for this purpose an alkali metal, such for example, potassium.

The accompanying drawing illustrates one practical form of apparatus to which my invention is applicable, namely an incandescent cathode discharge device provided with means for introducing the desired reagent.

The device shown in the drawing which may be used for rectifying alternating current, comprises an envelope 1 consisting of a glass not chemically attacked by alkali metal provided with a cathode 2 consisting for example of thoriated tungsten, and a cylindrical or cup-shaped anode 3, also consisting of a highly refractory metal, such for example, as tungsten. A heating current may be conveyed to the cathode by leading-in conductors 4, 5, sealed into a stem 6 in the usual manner and connected to a threaded socket 7 similar to an incandescent lamp socket. The anode stem 8 is also sealed into a glass stem 9 and attached to an external metal cap 10.

The cathode 2 is prepared by adding a thorium compound, such as nitrate of thorium to the oxide of tungsten before reduction of the metal, or by adding either thorium nitrate or thoria to the metal powder after reduction, but before consolidation of the metal powder by sintering and mechanical working to the solid state as described, for example by reference to thoriated tungsten in U. S. patent # 1,082,933. The proportion of thoria in the unsintered metal usually varies from 1/2 to 10% but in some cases may be even greater. The proportion of thorium compound within the above limits makes little difference in the maximum electron emission that may be obtained under the best conditions but the favorable conditions will be more easily attained with a greater than with a lesser amount.

The preliminary evacuation of the envelope is carried out by the usual methods of producing a non-striking high vacuum, which includes baking out the envelope to remove water vapor. The final stage of the evacuation is preferably but not necessarily carried out by a Gaede molecular pump to the highest possible vacuum obtainable by this means, that is, to about .001 micron. While the apparatus is still on the pump the cathode 2 is heated to a temperature of about 2000° K. (2727° C.) for a short time and the envelope 1 is baked out in an oven at a temperature of about 350 to 450° C.

The substance to be distilled into the envelope, for example, potassium, is indicated at 12 in a small side chamber 13, a small quantity of glass particles, or glass wool, 14 being preferably placed in front of the reducing material. As already indicated all glasses (including the glass wool) used in the apparatus should be unattacked by alkali metal. When the envelope is baked out care should be exercised not to heat the chamber 13 to too high a temperature. The potassium, or other material, is transferred by melting into a communicating chamber 15, after which the chamber 13 may be sealed off. Thereupon, the material is distilled into a second communicating chamber 16 and finally a very small amount is introduced into the main envelope 1, both the chambers 15, 16 being successively sealed off. The redistillation of the reducing material serves to purify it. Altho alkali metals have been indicated as preferable for the purposes of my invention, other reducing materials may be used, for example, hydrocarbon compounds. The bulb is finally sealed from the vacuum system at the contraction 11.

The thoriated cathode 2 is now heated to about 2900° K for about one minute. The treatment of the filament at this temperature appears to be desirable for purifying the surface of the cathode. The cathode is then incandesced within the range of about 2000° to 2400° K and by this temperature treatment some change is produced in the cathode which enormously increases its electron-emitting property under the condition described. The greatest activity is obtained between about 2200° to 2800° K. and the treatment at this temperature is usually continued for about one minute. Apparently a concentration of metallic thorium or of some other oxidisable thorium material takes place on the surface of the filament. The filament 2 may now be used as a cathode at or below this forming temperature.

The presence of the reducing agent in the main receptacle maintains the thorium reduced in spite of traces of water vapor which may be liberated from the glass. In any event the high electron emissivity of the thoriated cathode is more easily secured and maintained in the presence of the reducing agent than without it.

With a filament thus prepared I have obtained at a temperature of about 1300° to 1380°K substantially the same electron emission per sq. cm. as with a pure tungsten filament at about 2000°K. that is, about three milliamperes per sq. cm. A thoriated cathode may be operated around 1700° to 1800°K., at which temperatures its life is long, and thermionic current may be obtained many thousands of times greater than obtainable with pure tungsten at the same temperature.

Subsequently heating the filament to a higher temperature, for example, to 2300°K. causes some change, apparently a distillation of the film of thorium from the surface, as the electron emitting power of the cathode falls to the same order of magnitude as pure tungsten. When the cathode after being thus heated is re-subjected to a temperature of 2200° to 2500°K the active condition is restored.

The vapor pressure of potassium, sodium or other alkaline metal at room temperature is so low that objectionable positive ionization of its own vapor during the operation of the pure electron device is negligible and the vapor pressure of the oxidation products ~~production~~ of the alkaline metal have no

Per A

perceptible vapor pressure. For this reason, the alkali metals are to be preferred to carbonaceous compounds as reducing agents in the present device.

The vapor of alkaline metals does not produce an increased emission of a pure tungsten filament thereby furnishing proof that the beneficial effect of the alkaline metal is exerted upon thoria content of the filament and is not due to some ionization phenomena.

Under carefully controlled conditions the benefit of the increased electron emission of a thorium-containing cathode may be secured in a device filled with an inert gas, such, for example, as argon or other monatomic gases, at pressures ranging from a few millimeters of mercury pressure upward, in the presence of potassium or equivalent material for preventing the oxidation of thorium. Care must be exercised to have the cathode at a high enough temperature with reference to the current transmitted so that the vicinity of the cathode is surrounded by free electrons. In other words, the electron emission should be greater than necessary to convey the current thereby preventing a removal of the active thorium material on the surface of the cathode by a bombardment of positive ions.

What I claim as new and desire to secure by Letters Patent of the United States, is:-

1. An electrical discharge device comprising electrodes, one of which contains thorium, an inclosing envelop~~e~~ the space within which is evacuated to a pressure so low that positive ionisation is substantially absent, and a quantity of a vaporizable reagent capable of preventing the oxidation of thorium in communication with the space within said envelop~~e~~.

2. In an electrical discharge device, an inclosing envelop~~e~~, a quantity of alkali metal within said envelop~~e~~, and electrodes therein, one of which comprises in part at least, oxidizable thorium material, said electrodes having at a temperature of ~~about~~ 1500 to 1800° absolute an electron emission substantially equal to that of tungsten at about 2000° absolute.

3. In an electrical discharge device, an inclosing envelop~~e~~, a quantity of potassium within said envelop~~e~~, and electrodes therein, one of which consists largely of tungsten and containing thorium, said electrode having an electron emissivity at a given temperature materially greater per unit surface than tungsten at the same temperature.

4. An electrical discharge device comprising electrodes, one of which consists of metallic tungsten and a thorium material in an oxidizable state, an inclosing envelop~~e~~, and a quantity of a vaporizable reagent within said envelop~~e~~ capable of preventing the oxidation of thorium at an elevated temperature.

5. The process of improving the operation of an

electron discharge apparatus containing an electrode operating at incandescence comprising a highly refractory metal and a thorium material which consists in bringing into contact with said electrode the vapor of a reagent preventing the oxidation of thorium at an elevated temperature.

6. The process of improving the operation of an electron discharge apparatus containing an electrode of tungsten and thorium operating at incandescence in a non-striking vacuum, which consists in bringing into contact with said electrode the vapor of an alkali metal at a pressure too low to cause appreciable positive ionisation phenomena.

DEPARTMENT OF THE INTERIOR

UNITED STATES PATENT OFFICE

WASHINGTON Apr. 18, 1916.

Mr. Albert G. Davis,
C/o General Electric Co.,
Schenectady, N. Y.

Please find below a communication from the EXAMINER in charge of the application of

I. Langmuir, S. No. 58,377, filed Oct. 28, 1915, Electron Discharge Apparatus and Method of Operating the Same.

Thomas Ewing
Commissioner of Patents.

This application has been examined.

Page 4, last line, is the fourth word correct?

The following art is made of record:

British patent, 15,788 of 1914, (3 sheets),
    250-27,
Soddy, 859,021, July 2, 1907, 250-34,
Skaupy, 1,160,661, Nov. 16, 1915, 250-34,
Dwyer, 596,654, Jan. 4, 1898, 250-24,
Liebmann, 1,166,464, Jan. 4, 1916, 250-34,✓
Blau, 674,754, May 21, 1901, 250-34,
Stearn, 613,090, Oct. 25, 1898, 250-35,X.

The claims are rejected upon Dwyer, above, in view of British patent 15,788 of 1914. It is very common to make an electrode of thorium or a thorium compound. See, for example, Stearn. Dwyer discloses the idea of supplying a reducing agent such as sodium or potassium vapor introduced into the tube. Modifying the structure of British patent 14,788 of 1914, accordingly, is not considered invention.

The claims are also rejected on Soddy, above, who discloses the use of calcium to react chemically with any oxygen in a vacuum tube. The use of potassium instead of calcium is an obvious expedient.

The claims are rejected.

Examiner, Division XVI

PAPER NO. 8
AMENDMENT a

UNITED STATES PATENT OFFICE

In re Application of :
IRVING LANGMUIR, :
Serial No. 58,377, : ELECTRON DISCHARGE APPARATUS AND METHOD OF OPERATING THE SAME
Filed October 28, 1915, :
Div. 16, Room 109. :

Honorable Commissioner of Patents,

Sir:-

In response to the Office Action of April 18, 1916, please amend the above-entitled application as follows:-

Page 4, line 32, cancel "production" and substitute - products -

Add the following claims:

7. An electrical device comprising the combination of a sealed evacuated envelope, a refractory cathode, means for heating said cathode to incandescence, a coöperating anode and a quantity of potassium within said envelope.

8. An electrical device comprising the combination of an evacuated envelope, a cathode, an anode and a quantity of alkali metal enclosed within said envelope, and means for heating said cathode to incandescence.

REMARKS

The invention claimed in this application should not be regarded as an improvement in the method of producing vacua. It is an improvement in electrical devices operating by the thermionic discharge from an incandescent cathode. It is true that thermionic discharge devices are not broadly new, as shown by British patent

#15,788 of 1914, but this does not preclude further improvements being made in a device of this character.

Stearn patent #613,090 does not describe a thermionic device, and a disclosure with reference to the "vacuum" regulation of Crookes tube device can have no possible bearing on the operation of a thermionic device, in which the cathode emits electrons independently of ionisation of residual gas.

Dwyer patent #956,654 refers to the production of a vacuum by absorbing ammonia-gas with sodium or potassium vapor, but does not have the remotest connection with incandescent cathode devices.

The other patents cited, for example, Soddy patent #869,021, describing methods of obtaining good vacuum, and the Liebmann lamp getter patent #1,166,464, do not teach anyone a thing with reference to the effect of potassium or the like on a heated electron-emitting cathode.

The claims have not been amended as applicant's attorney does not perceive in what manner the references can either singly or in combination properly be used to anticipate the claims. It is not inconsistent with the fact that hot cathode devices broadly are old to this applicant and that sodium and potassium have formerly been used in the production of vacua, that a new improvement may be made in hot cathode devices involving the use of sodium, potassium, or the like. For example, when these devices are operated at a suitable voltage in the presence of such an amount of residual gas that positive ionisation is possible, then there is danger of destroying, or, at least, injuring the cathode by what is known as bombardment by positive ions. The substances described in the application, particularly so, potassium, seem to have little or no effect in disintegrating the cathode, but on the other hand these substances prevent the deleterious effect of gases such as water vapor.

Two additional claims have been added to better protect applicant's invention.

Reconsideration and allowance are respectfully requested.

Respectfully submitted,

Albert G Davis

Attorney for Langmuir.

Schenectady, N. Y.
February 13, 1917.

DEPARTMENT OF THE INTERIOR

UNITED STATES PATENT OFFICE

WASHINGTON March 26, 1917.

Irvin Langmuir, Assor.

Sir: Your APPLICATION for a patent for an IMPROVEMENT in Electron Discharge Apparatus and Method of Operating the Same, filed Oct. 28, 1915, has been examined and ALLOWED.

The final fee, TWENTY DOLLARS, must be paid not later than SIX MONTHS from the date of this present notice of allowance. If the final fee be not paid within that period, the patent on this application will be withheld, unless renewed with an additional fee of $15, under the provisions of Section 4897, Revised Statutes.

The office delivers patents upon the day of their date, and on which their term begins to run. The printing, photolithographing, and engrossing of the several patent parts, preparatory to final signing and sealing, will require about four weeks, and such work will not be undertaken until after payment of the necessary fee.

When you send the final fee you will also send, DISTINCTLY AND PLAINLY WRITTEN, the name of the INVENTOR, TITLE OF INVENTION, AND SERIAL NUMBER AS ABOVE GIVEN, DATE OF ALLOWANCE (which is the date of this circular), DATE OF FILING, and, if assigned, the NAMES OF THE ASSIGNEES.

If you desire to have the patent issue to ASSIGNEES, an assignment containing a REQUEST to that effect, together with the FEE for recording the same, must be filed in this office on or before the date of payment of final fee.

After issue of the patent uncertified copies of the drawings and specifications may be purchased at the price of FIVE CENTS EACH. The money should accompany the order. Postage stamps will not be received.

Final fees will NOT be received from other than the applicant, his assignee or attorney, or a party in interest as shown by the records of the Patent Office.

Respectfully,

Thomas Ewing
Commissioner of Patents.

Albert G. Davis,
℅ General Electric Co.,
Schenectady, N. Y.

IN REMITTING THE FINAL FEE GIVE THE SERIAL NUMBER AT THE HEAD OF THIS NOTICE.

UNCERTIFIED CHECKS WILL NOT BE ACCEPTED.

UNITED STATES PATENT OFFICE.

IRVING LANGMUIR, OF SCHENECTADY, NEW YORK, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

ELECTRON-DISCHARGE APPARATUS AND METHOD OF OPERATING THE SAME.

1,244,217. Specification of Letters Patent. **Patented Oct. 23, 1917.**

Application filed October 28, 1915. Serial No. 58,277.

To all whom it may concern:

Be it known that I, Irving Langmuir, a citizen of the United States, residing at Schenectady, in the county of Schenectady, State of New York, have invented certain new and useful Improvements in Electron-Discharge Apparatus and Methods of Operating the Same, of which the following is a specification.

The present invention relates to electrical devices having an electrode consisting at least in part of thorium and having at a given temperature an electron emission per unit surface materially greater than the emission of a refractory metal such as tungsten at the same temperature independently of and in the absence of positive ionization. These devices are described and claimed in a copending application, Serial No. 851,095, of July 15, 1914, renewed on June 25, 1917, as application Serial No. 176,926, to which the present application is closely related.

In the preparation of these devices great care must be exercised to remove the last traces of oxygenous gases, particularly water vapor, and precautions must be observed not to evolve water vapor from the bulb walls during the operation of the device.

In accordance with my present invention, I have improved the above described device and also rendered easier the preparation of the same by providing in the envelop a quantity of a vaporizable reagent of low vapor pressure capable of preventing the oxidation of thorium. I prefer to use for this purpose an alkali metal, such for example, as potassium.

The accompanying drawing illustrates one particular form of apparatus to which my invention is applicable, namely, an incandescent cathode discharge device provided with means for introducing the desired reagent.

The device shown in the drawing which may be used for rectifying alternating current, comprises an envelop 1 consisting of a glass not chemically attacked by alkali metal provided with a cathode 2 consisting for example of thoriated tungsten, and a cylindrical or cup-shaped anode 3, also consisting of a highly refractory metal, such for example, as tungsten. A heating current may be conveyed to the cathode by leading-in conductors 4, 5, sealed into a stem 6 in the usual manner and connected to a threaded socket 7 similar to an incandescent lamp socket. The anode stem 8 is also sealed into a glass stem 9 and attached to an external metal cap 10.

The cathode 2 is prepared by adding a thoria compound, such as nitrate of thorium to the oxid of tungsten before reduction of the metal, or by adding either thorium nitrate or thoria to the metal powder after reduction, but before consolidation of the metal powder by sintering and mechanical working to the solid state as described, for example by reference to thoriated tungsten in U. S. Patent #1,082,933. The proportion of thoria in the unsintered metal usually varies from ½ to 10% but in some cases may be even greater. The proportion of thorium compound within the above limits makes little difference in the maximum electron emission that may be obtained under the best conditions but the favorable conditions will be more easily attained with a greater than with a lesser amount.

The preliminary evacuation of the envelop is carried out by the usual methods of producing a non-striking high vacuum, which includes baking out the envelop to remove water vapor. The final stage of the evacuation is preferably but not necessarily carried out by a Gaede molecular pump to the highest possible vacuum obtainable by this means, that is, to about .001 micron. While the apparatus is still on the pump the cathode 2 is heated to a temperature of about 2900° K. (2727° C.) for a short time and the envelop 1 is baked out in an oven at a temperature of about 360 to 450° C.

The substance to be distilled into the envelop, for example, potassium, is indicated at 12 in a small side chamber 13, a small quantity of glass particles, or glass wool, 14 being preferably placed in front of the reducing material. As already indicated all glasses (including the glass wool) used in the apparatus should be unattacked by alkali metal. When the envelop is baked out care should be exercised not to heat the chamber 13 to too high a temperature. The potassium, or other material, is transferred by melting into a communicating chamber 15, after which the chamber 13 may be sealed off. Thereupon, the material is distilled into a second communicating chamber 16 and finally a very small amount is introduced into the main envelop 1, both the chambers 15, 16 being successively sealed off. The redistillation of the reducing material serves to purify it. Although alkali metals have been indicated as preferable for the purposes of my invention, other reducing materials may be used, for example, hydrocarbon compounds. The bulb is finally sealed from the vacuum system at the contraction 11.

The thoriated cathode 2 is now heated to about 2900° K. for about one minute. The treatment of the filament at this temperature appears to be desirable for purifying the surface of the cathode. The cathode is then incandesced within the range of about 2000° to 2400° K. and by this temperature treatment some change is produced in the cathode which enormously increases its electron-emitting property under the condition described. The greatest activity is obtained between about 2200° to 2300° K. and the treatment at this temperature is usually continued for about one minute. Apparently a concentration of metallic thorium or of some other oxidizable thorium material takes place on the surface of the filament. The filament 2 may now be used as a cathode at or below this forming temperature.

The presence of the reducing agent in the main receptacle maintains the thorium reduced in spite of traces of water vapor which may be liberated from the glass. In any event the high electron emissivity of the thoriated cathode is more easily secured and maintained in the presence of the reducing agent than without it.

With a filament thus prepared I have obtained at a temperature of about 1800° to 1880° K. substantially the same electron emission per sq. cm. as with a pure tungsten filament at about 2000° K., that is, about three milliamperes per sq. cm. A thoriated cathode may be operated around 1700° to 1800° K., at which temperatures its life is long, and thermionic current may be obtained many thousands of times greater than obtainable with pure tungsten at the same temperature.

Subsequently heating the filament to a higher temperature, for example, to 2800° K. causes some change, apparently a distillation of the film of thorium from the surface, as the electron emitting power of the cathode falls to the same order of magnitude as pure tungsten. When the cathode after being thus heated is re-subjected to a temperature of 2200° to 2300° K. the active condition is restored.

The vapor pressure of potassium, sodium or other alkaline metal at room temperature is so low that objectionable positive ionization of its own vapor during the operation of the pure electron device is negligible and the vapor pressure of the oxidation products of the alkaline metal have no perceptible vapor pressure. For this reason, the alkali metals are to be preferred to carbonaceous compounds as reducing agents in the present device.

The vapor of alkaline metals does not produce an increased emission of a pure tungsten filament thereby furnishing proof that the beneficial effect of the alkaline metal is exerted upon thoria content of the filament and is not due to some ionization phenomena.

Under carefully controlled conditions the benefit of the increased electron emission of a thorium-containing cathode may be secured in a device filled with an inert gas, such, for example, as argon or other monatomic gases, at pressures ranging from a few millimeters of mercury pressure upward, in the presence of potassium or equivalent material for preventing the oxidation of thorium. Care must be exercised to have the cathode at a high enough temperature with reference to the current transmitted so that the vicinity of the cathode is surrounded by free electrons. In other words, the electron emission should be greater than necessary to convey the current thereby preventing a removal of the active thorium material on the surface of the cathode by a bombardment of positive ions.

What I claim as new and desire to secure by Letters Patent of the United States, is:—

1. An electrical discharge device comprising electrodes, one of which contains thorium, an inclosing envelop the space within which is evacuated to a pressure so low that positive ionization is substantially absent, and a quantity of a vaporizable reagent capable of preventing the oxidation of thorium in communication with the space within said envelop.

2. In an electrical discharge device, an inclosing envelop, a quantity of alkali metal within said envelop, and electrodes therein, one of which comprises in part at least, oxidizable thorium material, said electrodes having at a temperature of about 1800 to 1880° absolute an electron emission substantially equal to that of tungsten at about 2000° absolute.

3. In an electrical discharge device, an inclosing envelop, a quantity of potassium within said envelop, and electrodes therein, one of which consists largely of tungsten and containing thorium, said electrode having an electron emissivity at a given temperature materially greater per unit surface than tungsten at the same temperature.

4. An electrical discharge device comprising electrodes, one of which consists of metallic tungsten and a thorium material in an oxidizable state, an inclosing envelop, and a quantity of a vaporizable reagent within said envelop capable of preventing

the oxidation of thorium at an elevated temperature.

5. The process of improving the operation of an electron discharge apparatus containing an electrode operating at incandescence comprising a highly refractory metal and a thorium material which consists in bringing into contact with said electrode the vapor of a reagent preventing the oxidation of thorium at an elevated temperature.

6. The process of improving the operation of an electron discharge apparatus containing an electrode of tungsten and thorium operating at incandescence in a non-striking vacuum, which consists in bringing into contact with said electrode the vapor of an alkali metal at a pressure too low to cause appreciable positive ionization phenomena.

7. An electrical device comprising the combination of a sealed evacuated envelop, a refractory cathode, means for heating said cathode to incandescence, a coöperating anode and a quantity of potassium within said envelop.

8. An electrical device comprising the combination of an evacuated envelop, a cathode, an anode and a quantity of alkali metal inclosed within said envelop, and means for heating said cathode to incandescence.

In witness whereof, I have hereunto set my hand this 27th day of October, 1915.

IRVING LANGMUIR.

PETITION

To the Honorable Commissioner of Patents:

Your petitioner, IRVING LANGMUIR

a citizen of THE UNITED STATES, residing at SCHENECTADY

in the County of SCHENECTADY, State of NEW YORK

whose Post Office address is c/o GENERAL ELECTRIC CO., SCHENECTADY, N.Y.

prays that Letters Patent may be granted him for the improvement in

ELECTRON EMITTING CATHODES AND METHODS OF PREPARATION

(DOCKET NO. 28,408)

set forth in the accompanying specification.

And he further prays that you will recognize Mr. Albert G. Davis, of Schenectady, New York, as his attorney, with full power of substitution and revocation, to prosecute this application, to make alterations and amendments therein, to receive the patent, and to transact all business in the Patent Office connected therewith.

Irving Langmuir

[illegible]

TO ALL WHOM IT MAY CONCERN:

BE IT KNOWN, that I, IRVING LANGMUIR, a citizen of the United States, residing at Schenectady, in the County of Schenectady, State of New York, have invented certain new and useful Improvements in ELECTRON-EMITTING Devices ~~CATHODES~~ AND METHODS OF PREPARATION, of which the following is a specification.

Per D

This invention comprises an improvement in the electron emitting cathodes of the type described in my prior U. S. Patents Nos. 1,244,216 and 1,244,217.

Per C

In these patents I have described the preparation and advantages of a vacuum tube containing a cathode adapted to be operated at incandescence and containing distributed throughout its mass thorium (or a compound of thorium) as a constituent. This type of electrode consists of a refractory conducting material, such for example as tungsten, with an addition of thoria, the latter being subjected to modifications during the preparation of the cathode in the electron discharge device so that the active material in a finished device according to all indications, consists of metallic thorium or at least of a lower oxide of thorium than thoria (Th O2). The cathode prepared according to the methods set forth in my first patent 1,244,216 which is commonly known as a "thoriated cathode", is very sensitive to traces of oxidizing gas in the bulb, as for example, small traces of water vapor which may be given off from the walls of the bulb during the normal operation of the device. In order to prevent loss of activity of the cathode, I have described in my second patent No. 1,244,217, the beneficial results obtained by the admission to the bulb of a small amount of alkali metal, such as potassium or sodium, or of a hydrocarbon compound.

Per B

Insert C'

D

My present invention in one of its aspects is based on the discovery that carbon in a ~~thoriated~~ cathode of the thoriated type when present in a definitely limited amount, will prevent not only reoxidation of active thorium material but what is more important, will act beneficially to reduce thoria to the active state. Although the thoriated cathodes described in my prior patents can be used with satisfactory results, I have found that a further improvement in regularity and stability can be effected by using carbon as hereinafter described, not only as in accordance with my prior patent in restricted quantities, as an oxidation preventing agent, but, as hereinafter described, as an ingredient of a thoriated cathode.

Per C

D

¶ In accordance with another feature of my invention my improved cathode is used in conjunction with a non-carbonaceous reducing agent which is provided in the bulb, as for example, a highly oxidizable metal.

Per B

Insert B'

B' ~~Another feature of my invention comprises the combination with a thoriated cathode of a reducing agent having a materially lower vapor pressure than the alkali metals.~~ My invention will be pointed out with greater particularity in the accompanying claims and described fully in conjunction with the accompanying drawing which shows somewhat diagrammatically ~~the~~ an apparatus used for carrying out the preparation of an incandescent cathode rectifier.

D

The rectifier shown in the figure is illustrative of one of the various forms of incandescent cathode devices. It consists of a bulb 1 containing a filamentary cathode 2 into which thoria has been introduced as described in my above mentioned prior patents, and an anode 3, consisting of tungsten, molybdenum or other suitable material. These electrodes are respectively connected to lead wires 4, 4' and 5 sealed into the walls of the bulb. The bulb is connected to the usual pumping system by means of a tubulature 6. The bulb also communicates with an elongated tube 7 adapted to be surrounded by a freezing mixture contained within a double-walled receptacle 8.

In carrying out my invention, the bulb 1 is first baked out as usual to remove water vapor and is then exhausted. Within the tube 7 is placed a substance adapted to give a low pressure of carbonaceous vapor, as for example, anthracene ($C_{14}H_{10}$) or naphthalene ($C_{10}H_8$).

When the vapor pressure of the substance employed is relatively high, I prefer to reduce the pressure of the hydrocarbon vapor in the bulb 1 by surrounding the tube with a freezing agent contained in ~~a~~ the receptacle 8. When employing naphthalene, which has a moderately high vapor pressure, ~~I~~ prefer to reduce the temperature of the containing tube ~~6~~ 7 to about -20 to -30°C. to reduce the vapor pressure to about 0.1 to 0.01 microns. The bulb 1 which communicates with the side tube 7, therefor, is filled with hydrocarbon vapor at approximately this pressure. The quantity of hydrocarbon may be controlled by one or more constrictions, such as 9, 10 which may regulate the pressure with or without a freezing agent.

The filament 2, which preferably consists of metallic tungsten, containing about 3/4% thoria, is heated to a temperature of about 2300°K. (2000°C.) for a few minutes, in contact with the hydrocarbon vapor. At this temperature the incandescent filament decomposes the hydrocarbon vapor which comes in contact with the incandescent surface of the tungsten and causes the chemical combination with the tungsten of the carbon set free from the naphthalene vapor, with the formation of tungsten

Per D

Per A

carbide (W_2C). The heating is continued for a length of time ~~and was~~ sufficient ~~[illegible]~~ to give an increase in resistance of about 15 to 25% of the tungsten filament when cold, or at room temperature. This change in resistance corresponds to the presence of about two-thirds per cent of carbon by weight in the filament.

The carbon content most beneficial will vary with the conditions. In the case of a thoriated tungsten cathode all of the metallic tungsten will be converted to brittle tungsten carbide (W_2C) with a carbon content as high as 3%. Ordinarily a carbon content as high as about 1% is as high as permissible without unduly weakening the cathode. Although the presence of even minute amounts of carbon is highly undesirable in an incandescent lamp, a ~~reasonably~~ commercially long life can be obtained in a thoriated cathode containing carbon, as the cathode need be operated only at a relatively low temperature, say at about the operating temperature of an ordinary carbon lamp, the electron emissivity of a thoriated cathode being so much greater than that of an ordinary pure tungsten cathode. The hydrocarbon vapor is removed from contact with the filament either by sealing off the tube 7 at the contraction 9 or cooling the side tube 7 by means of liquid air in the receptacle 8 to a temperature so low that the vapor pressure of the naphthalene is negligible, thereby removing the naphthalene vapor from the bulb 1.

Per B

In some cases carbon to a desired proportion may be combined with the cathode prior to the introduction of the cathode into the bulb 1. For example, a thoriated filament may be prepared by squirting tungsten and thoria with a carbonaceous binder in amounts adapted to leave a suitable restricted proportion of carbon in the finished product.

104

As the next step in the preparation of the device, the anode 3 is deprived of gases by the usual method of electron bombardment; that is, by passing a discharge between the cathode at ~~[illegible]~~ incandescence and the anode, the exhaust pump in the meantime being operated to remove the vapors and gases which are liberated. During this step some of the carbon is removed by oxidation and evaporation from the cathode but with an original carbon content of about 2/3 of one per cent, enough carbon remains subsequently to furnish a supply of active thorium material by reduction of the thoria.

Per D

D

D

Per B

Insert B²

Insert B³

(7) B² ~~As the next step in carrying out my invention,~~ a non-carbonaceous ~~reducing~~ material (8) B³ may be introduced into the bulb. In some cases this non-carbonaceous reducing agent may consist of alkali metal, such as sodium or potassium. Caesium may be used to advantage in some cases, especially when some positive ionization is desired in the electron discharge device. Caesium can be conveniently provided by adding a mixture of caesium halide and metallic calcium as a paste to some part of the bulb. (14) a'

Insert a'

When not desiring ionization of residual gases or vapors, I prefer for the reasons given above to introduce a reagent having a lower vapor pressure than the alkali metals, as for example, alkaline earth metal such as magnesium, calcium, strontium, or the like. Conveniently this is done by providing within the bulb a small heating coil 11, consisting of tungsten or other suitable refractory material, and containing a small quantity of the metal to be vaporized. Preferably I employ metallic magnesium. By ~~When~~ heating the tungsten filament 11 with ~~by~~ current conducted thru the lead wires 4, 12, some of the magnesium is volatilized and deposited on the inner surface ~~walls~~ of the bulb which is then sealed off at the contraction 10. As during the sealing off process there is a tendency

B

D

Per a

D

D

C

to drive out a small quantity of gas from the heated glass, I prefer to heat up the filament 11 the second time, to volatilize a small additional quantity of magnesium, or the like, in order to combine chemically with what little gas may have gotten into the bulb during the sealing off operation.

The film of magnesium, or other equivalent metal, on the walls of the bulb will combine with any water vapor or oxygen which may be given off by the bulb, or any other parts of the device during its operation, and thereby prevent an oxidization of the active thorium material upon the surface of the cathode. ~~Unlike the alkali metals, a material of low vapor pressure such as magnesium, does not come into contact as a vapor with the cathode and take part in the reduction of thoria.~~

The tungsten cathode 2 is ~~also~~ preferably heated for a very short time to about 2700°K. to volatilize any thorium oxide on its surface.

As a final step, the ~~a~~ cathode is "activated ~~formed~~", that is, brought into its highly active state by heating to a temperature of about 2200°K. for a few minutes. This results in the reduction of thoria by the carbon and causes the active thorium product to come to the surface of the cathode where it will be effective in increasing the electron emission during the operation of the device. The tube is then ready for operation.

As explained in my prior patents, a temperature materially higher than the activating ~~forming~~ temperature will result in the thorium being volatilized from the surface of the cathode. A fresh supply can be produced and caused to accumulate upon the surface by again activating or "forming" an electrode at about 2200°K. During normal operation, the cathode is heated to a temperature below about 2200°K. and as high as 2100°K. Under these conditions, the electron emission stays constant.

What I claim as new and desire to secure by Letters Patent of the United States, is:-

Cl. 1-2

Sub ~~B7~~ C2

1. A cathode for an electric discharge device comprising a refractory metal and containing carbon and thorium as elementary constituents.

Per C

2. A cathode adapted to emit electrons at incandescence comprising tungsten, thoria and less than ~~3%~~ three percent by weight of carbon.

Per B

3. A cathode adapted to emit electrons at incandescence comprising tungsten, about ~~3/4%~~ three-quarters percent thoria and about ~~2/3%~~ two-thirds percent by weight of carbon.

" B

" B

4. The method of increasing the electron emissivity of an electrode of the thoriated type ~~operable at incandescence and comprising a refractory metal and thoria~~ which consists in introducing carbon into said electrode in amounts insufficient to convert said metal to a carbide, ~~and thereupon~~ sealing said electrode into a space substantially free from carbonaceous/vapors and thereupon activating said electrode.

" C

" B. " C

" B

5. An electric discharge device comprising an evacuated envelope, electrodes therein one of which comprises a refractory metal, thorium oxide and carbon, I C3 and a non-carbonaceous reagent capable of combining with ~~oxygenous~~ deleterious gases in said envelope.

Insert C3

" C

Cl. 6

Sub C4

6. An electric discharge device comprising an envelope, electrodes therein one of which consists of a highly refractory conducting material containing an oxide of thorium and ~~carbon, and a quantity of highly oxidizable metal therein capable of combining with traces of oxygenous gases.~~ B5

Insert B5

Per B

862 Ü

B C5 D B

7. An electric discharge device having a cathode comprising metallic tungsten, and thorium oxide ~~containing~~ combined with said tungsten C5 carbon ~~and thorium as constituents, and a quantity of magnesium in said device.~~

Cl. 8-9

i.e. B

B

8. The method of increasing the electron emissivity of ~~testing~~ an electrode comprising a refractory metal and thoria which consists in introducing carbon into said electrode, ~~and thereupon heating said conductor in a non-carbonizing and non-oxidizing environment to a temperature at which~~ B6 ~~chemical interaction occurs accompanied by a marked increase of electron emissivity.~~

id B6?

i A

id B7

B

9. The method of increasing the electron-emissivity of an electrode comprising a refractory metal and thoria which consists in introducing carbon into said electrode and B7 thereupon heating said conductor to about 2200° K. in a non-oxidizing environment. ~~in the presence of a non-carbonaceous reducing material.~~

C

id C7

10. The method of preparing an electrode adapted to emit electrons at incandescence which consists in heating a conductor comprising refractory metal and thoria in a carbonaceous vapor to a temperature adapted to cause combination of carbon with said conductor, ~~there-~~upon removing said vapor, E7 and heating said conductor in a non-oxidizing environment to a temperature at which electron emissivity is markedly increased.

id C8

11. The method of preparing an electrode adapted to emit electrons at incandescence which consists in heating to incandescence a conductor comprising tungsten and thoria in a carbonaceous vapor until a marked increase in cold resistance occurs, C8 and heating said conductor in the absence of said vapor in a reducing environment to

produce a surface layer of thorium material having a markedly higher electron emissivity than the original conductor.

Cl. 12-14

Sub C9

12. An electrical discharge device comprising an enclosing envelope, a quantity of metal therein having a chemical affinity for water vapor and having a materially lower ~~higher~~ vapor pressure than the metals of the alkali group and electrodes therein, one of which contains thorium as a constituent.

Per A

13. An electrical discharge device comprising an enclosing envelope, a quantity of magnesium ~~therein~~ deposited on said envelope, and electrodes ~~therein~~, one of which contains thorium as a constituent.

DEPARTMENT OF THE INTERIOR

UNITED STATES PATENT OFFICE

WASHINGTON August 3, 1922

Mr. Albert G. Davis,
General Electric Co.,
Schenectady, N. Y.

Please find below a communication from the EXAMINER in charge of the application of

Irving Langmuir, Ser. #491,634, filed Aug. 11, 1921.

Electron Emitting Cathodes and Methods of Preparation.

Thomas E. Robertson
Commissioner of Patents.

This application has been examined.

Page 4, line 2, insert and was preceding "formed".

Record is made of

DE LODYGUINE,	575,668,	Jan. 19, 1897,	176-130;
McQUAT ET AL,	869,012,	Oct. 22, 1907,	176-130;
THOWLESS,	982,751,	Jan. 24, 1911,	176-131.

Claim 13 is rejected as defining nothing patentable over THOWLESS, noting that, in Fig. 3 thereof, element F comprises in part thorium while element E may be made of magnesium.

All other claims appear allowable.

In claim 9, line 2, insert of before "electrode".

Insert B16

25. A cathode material for electrical discharge devices consisting largely of a metal capable of operation at an elevated temperature, a reducible compound of a material of high electron emissivity and less than about one per cent of carbon.

Ang.

REMARKS

The references cited relate to the manufacture of filaments or glowers for lighting purposes whereas applicant's invention relates to the manufacture of an efficient electron emitter. The former is operated at the highest incandescence consistent with a fair commercial life. The latter is operated at the lowest temperature consistent with efficient operation of the electron tube.

872

D 119

McQuat & Lorenz patent 959,012 describes a process of making a carbon incandescent filament provided with a coating of carbon and metal. DeLodyguine describes a flashing process of making a composite metal filament and Thowless patent 962,751 describes a method of making incandescent glowers which entail the use of magnesium only as a temporary element which is removed before use of the filament. If the magnesium were removed by volatilization in the lamp bulb an inoperative lamp would result due to the opaque magnesium "mirror" deposited on the bulb. In subject matter and in terms of the claims, this case relates to an art which has very few points of contact with the lamp art. Even if a filament useful for lighting were found useful unchanged as an electron emitter this discovery probably would involve a patentable invention. Claim 13 specifically calls for an "electrical discharge device" and electrodes are specified as part of the combination. These are not found in the Thowless lamp. The claim has been further amended to distinguish clearly over this reference. However, to protect applicant's invention a number of more generic claims are submitted herewith.

An allowance is solicited.

Respectfully submitted,

Alexander S. Lunt

Attorney for Langmuir.

FJH:LBG

DEPARTMENT OF THE INTERIOR

UNITED STATES PATENT OFFICE

WASHINGTON

February 13, 1924

Mr. Alexander D. Lunt,
General Electric Co.,
Schenectady, N. Y

Please find below a communication from the EXAMINER in charge of the application of

Irving Lnagmuir, Ser. #491,634, filed Aug. 11, 1921.

Electron Emitting Cathodes and Methods of Preparation.

Thomas E. Robertson
Commissioner of Patents.

This action is responsive to amendment filed May 29, 1923.

A claim is a formal definition of the invention, and the numerical percent abbreviations should be expanded in the first few claims.

Page 5, line 23 is objected to as misdescriptive in that "magnesium" is not "an alkaline earth metal". Obviously, applicant intended the insertion of the amendment after "magnesium".

Applicant should observe proper line of demarcation between this application and his patents.

Cancelation of claims in the amendment such as 17, specific to the use of "alkaline earth metals" is required since applicant has elected to claim the magnesium species.

Claim 13 is rejected as aggregative since the magnesium getter apparently does not patentably cooperate with the cathode, but merely acts on the gas content of the tube as in the lamp art. It is old to use magnesium as a getter, as shown by

WHITE, 1,159,307, Nov. 2, 1915, 250-27; or
MACKAY, 1,208,597, Dec. 12, 1916, 250-27.

It is obvious that, after the getter has been vaporized within the tube, the excess would condense on the walls. However, this makes no difference patentably so long as it is exposed to the gases and positioned somewhere within the enclosure, e.g. on the leads as shown by Mackay. As to water vapor, see line 32, page 1 of Mackay. The patent to LEDERER, 1,461,360, July 10, 1923, 176-122; shows it old to coat the walls of a tube with a getter. It is old to use thorium in an electrode as shown by

LANGMUIR, 1,244,216, Oct. 23, 1917, 250-27x;
LANGMUIR, 1,244,217, Oct. 23, 1917, 250-27x.

Upon reconsideration, all claims such as 5, 6, 7, etc., formerly allowed, are rejected as aggregative for the same reasons given in the rejection of claim 13. In claim 10, the last step is merely the ordinary step in the subsequent operation of any tube. In the event of a traverse of this rejection, these claims will be rejected as unpatentable over LANGMUIR in view of MACKAY or LEDERER, cited.

Attention is directed to page 2, lines 111 to 123, of LANGMUIR, 1,244,216, which states that a certain amount of carbon increases the emission and that too much would form a carbide. In view of this and the state of the art as above exemplified, it appears that applicant is entitled to nothing but specific claims to the use of carbon within the cathode as a reducing agent, and the nature of the invention in view of the art will not permit of such an excessive number of claims as now exists. Claims such as 14 are indefinite as to the materials used and as to their proportions.

Attention is called to LANGMUIR, 1,244,217, page 1, lines 64, 65, and page 2, lines 8, 34 to 37.

In view of page 4, lines 27 to 33, attention is called to lines 45 to 48 of patent to

COOLIDGE, 1,010,866, Dec. 5, 1911, 250-27.

Coolidge shows a combination of ingredients which may be used as "cathode material". It appears that some of the carbon would remain and reduce some of the thoria in a manner set forth by applicant.

It is noted that the patent to

VON RECKLINGHAUSEN, 946,068, Jan. 11, 1910, 250-27x;

uses magnesium as a getter and confines it - lines 71 to 79, page 1, - to the element 5, hence preventing its escape to other parts of the tube where it is not wanted. On the other hand, see lines 80 to 87.

Attention is called to page 2, lines 14 to 37, of

BLAU, 674,754, May 21, 1901, 250-27x;

disclosing a process of adding carbon to a filament by means of a carbonaceous vapor.

Exr., Div. 16.

In re Application of :

IRVING LANGMUIR :

Serial No. 491,634 : ELECTRON EMITTING CATHODES AND METHODS OF PREPARATION

Filed August 11, 1921 :

Div. 16, Room 112 :

B

Honorable Commissioner of Patents.

Sir:

In response to the Office Action of February 13, 1924, please amend the above entitled case as follows:

Page 1, line 13, after "containing" insert -distributed throughout its mass-

Page 2, line 14, after "agent" insert -which is provided-

Page 2, lines 16-19, cancel the sentence beginning with "Another" and ending with "metals" and substitute the following:

B' ita

-A thoriated cathode may be deleteriously affected by positive ion bombardment, that is, when voltages materially higher than the ionization voltages are impressed between a thoriated cathode and a positive electrode in the presence of ionizable gas, then the beneficial effect of the thorium may be largely or entirely destroyed by positive ion bombardment. Although the alkali metals are entirely satisfactory as agents to remove deleterious gases when the operating temperature of the bulb is only moderately above room temperature, as in the case of radio receiving tubes, these alkali metals have a sufficiently high vapor pressure at the operating temperature of power devices in which cathodes of the thoriated type are used to become ionized at

D

higher voltages and to cause removal of the active film of thorium from the cathode by bombardment. I have found that it is advantageous in many cases to provide a device containing a cathode of the thoriated type with a material having an affinity for gases, such as magnesium, for example, which at the operating temperature of the device, has substantially no vapor pressure.

Page 4, line 15, cancel "reasonably" and substitute -commercially-

Page 5, line 9, after "enough" insert -carbon-

Line 11, cancel "As the next step in carrying out my invention" and substitute -After the cathode has been provided with a content of reducing agent-

B2

Line 12, cancel "reducing" ; same line after "material" insert -capable of combining with water vapor and other deleterious gases-

B3

Line 21, after "introduce" insert -for the reasons given above-

Page 6, lines 12 to 15, cancel the sentence beginning with "Unlike" and ending with "thoria."

Line 15, indicate that sentence beginning with "The tungsten" should constitute a new paragraph.

Line 16, cancel "also."

Cancel Claim 1, and rewrite as follows:

B4

Sub. C 2

~~1. A cathode body for an electric discharge device comprising a refractory metal, containing thorium as an elementary constituent, and having carbon combined therewith, said body being characterised by a higher electrical resistance than a body~~

uncombined with carbon but which otherwise is similar, and being less sensitive to the deleterious effect of gases than a cathode body unprovided with carbon.

Claim 2, line 3, cancel "3%" and insert - three percent -.

Claim 3, line 2, cancel "3/4%" and insert - three-quarters percent -.

Line 3, cancel "2/3%" and insert - two-thirds percent -.

Claim 4, line 5, place a comma after "carbide" and cancel "thereupon."

Line 7, after "vapors" add - and thereupon activating said electrode -

Claim 6, line 4, cancel "carbon and a quantity of" and substitute" - a non-volatile material which is capable of reducing said oxide of thorium. -

B5 Rec C

Cancel lines 5 and 6.

Claim 7, line 2, after "tungsten" place a comma and insert - thorium oxide -.

Lines 3 and 4, cancel the matter beginning with "and thorium" and ending with "device", and substitute - combined with said tungsten -.

Claim 8, line 1, cancel "treating" and substitute - increasing the electron emissivity of -.

Line 3, place a comma after "electrode" and cancel "and thereupon".

Lines 5 to 7, cancel the matter beginning with "chemical" and ending with "emissivity" and substitute - a carbide of said metal is formed, activating said electrode by heating to about 2200° K. and operating the same under such conditions that bombardment of the electrode by positive ions is inappreciable -.

B6 Rec C

Claim 9, line 4, after "electrode" insert - in

B7 Rec

sufficient quantity to form an appreciable amount of carbide -.

Line 5, after "environment" place a period and cancel the rest of the claim.

Claim 14, line 1, after "cathode" cancel "material".

Incomplete & inaccurate?

Line 3, cancel "increasing" and substitute - cathode -; line 4, after "agent" insert the following: - contained in said cathode which is capable of forming a supply of said material of high emissivity during the life of said cathode, the amount of said agent being restricted to a proportion which will permit said cathode to be operated with a commercially long life. -

B8

Per C

Claim 15, line 4, cancel "3%" and substitute - three percent -.

Claim 16, line 7, before "to carbide" insert - completely -.

Claim 17, line 3, after "contains" insert - less than three percent of carbon combined therewith and -.

√ B9

Line 5, before "and" insert - but being sensitive to positive ion bombardment -.

√ B10

Claim 18, line 5, before "and" insert - but being sensitive to positive ion bombardment -.

√ B11

Claim 19, line 5, before "and" insert - but being sensitive to positive ion bombardment -.

√ B12

Claim 20, line 4, after "emissivity" insert - which when rendered active is sensitive to ion bombardment -.

√ B13

Claim 21, line 4, after "capable" insert - when activated -.

Line 7, after "oxidation" insert - and positive bombardment -.

Claim 22, line 5, before "water" insert

B14 -positive ion bombardment, and to the chemical effect of-

Line 9, after "pressure" insert -at the operating temperature of said device-

Claim 23, line 7, after "electrode" insert -completely-

Line 10, after "electrode" change the period to a comma, and add -and thereupon operating

15 said electrode under conditions which render the effect of positive ion bombardment of said electrode inappreciable-.

Claim 24, line 7, after "material" change the period to a comma and add the following -but being

16 capable of reducing a sufficient amount of said compound to enable said electrode to be more readily activated during use than would be the case in the absence of said carbon-.

REMARKS

The formal changes required by the Examiner in the first few claims have been made.

Reconsideration is requested of the Examiner's objection to the inclusion of magnesium with the alkaline earth metals. It is possible that some chemical writers have not included magnesium with the alkaline earths, but nevertheless according to the Century Dictionary and Webster's new International Dictionary, lime, magnesium, baryta and strontia are included in the alkaline earths, even though Webster states that properties of these metals fall between the true alkalies and the earths proper.

According to a more scientific chemical classification on the basis of Periodic System, magnesium is included in subgroup 1 of group 2, together with calcium, strontium, barium and magnesium; see for example, "Abegg's Handbuch der Anorganischen Chemie II, 2, and Smithsonian Physical Tables by Fowle, 7th edition, Page 410.

The claims in this case are rejected on eight different references, some of which are used in combination, and some singly. The invention constitutes an important improvement in a broad vacuum tube invention described in certain prior patents of the present inventor, Dr. Irving Langmuir; namely, 1,244,216, and 1,244,217, which were filed in 1914. The single fact that the production of radio tubes embodying the invention have run into the millions, is a sufficient indication of the commercial importance of the invention. The fact that the improvements herein claimed are in regular commercial use in the manufacture of vacuum tubes containing thoriated cathodes, speaks for itself and leaves no doubt as to the practical utility of the improvements.

The Examiner's reasoning in combining the references has not been stated very fully, but apparently he is of the opinion that the nature and constitution of the thoriated cathode is sufficiently described in the prior patents to render obvious the new features claimed herein.

A closer examination will show that this is not the case. It is true that by following the specifications of these patents good vacuum tubes can be made in which the high electron emissivity of thorium is utilized.

The present improvements extend the range of conditions under which the invention can be used, and increase the certainty of getting uniformly good results from day to day under manufacturing conditions. These improvements which are described [illegible] detail in the specification may be summarized briefly, as

First - The carburization of the thoriated filament, and

Second - The introduction of metallic magnesium into the evacuated bulb.

In prior patent 1,244,216 it is stated in lines 111 to 118, that the admission of a trace of hydrocarbon vapor to a tube containing a thoriated cathode is followed by a rise in electron emission, but the patent goes on to say that the electron emission drops to a low value when the carbon is in excess. The second patent 1,244,217 covers the addition of alkali metals such as potassium to a thoriated cathode tube, and states that in some cases, carbonaceous compounds can be used in place of alkali metal.

Mackay patent 1,208,597 describes an incandescent cathode arc device containing a filling of argon or similar gas at a pressure of about 5 to 12 c.m. Calcium or magnesium is placed in proximity to and receives the heat of the arc, thereby decreasing the drop of potential in the arc. The function of the magnesium, calcium, or the like, the patentee states, appears to be a combination with water vapor, hydrogen, or nitrogen.

It is always difficult after an improvement has been made to place oneself in the position of the person who is supposed to have been skilled in the art prior or at the time the invention was made. Such a person, in this case might be assumed to be the skilled manufacturer of vacuum tubes, who is familiar with the Langmuir patents, as well as the Mackay patents cited by the Examiner.

Suppose the electron emissivity of a thoriated cathode device containing an alkali metal was found to become impaired or destroyed under certain conditions, say, for power transmission.

Why should a person familiar with the prior patents, cited by the Examiner, conclude that if he were to substitute an alkaline earth metal for the alkali metal, the trouble would disappear. He would know that the conditions in the thoriated cathode tube device are utterly unlike the conditions of an arc tube, such as described in Mackay patent 1,208,597. In the arc device magnesium operates at comparatively high temperature in the presence of active positive ionization and its beneficial effect is to lower the arc drop (by the removal of gas producing inelastic collisions). From the prior Langmuir patent 1,244,217, he would know that he must remove water vapor and other deleterious gases to an unusual degree. He would know from the White patent 1,159,307 that magnesium or calcium vapor is one means of producing high vacua but as other methods of evacuation had already been used when preparing the tubes, why choose this particular agent, especially as the problem is not merely to produce a high vacuum, but to maintain a high vacuum. He would know that the alkaline earth metals are less chemically active than the alkali metals, and what is most significant, he would know that the former have substantially no vapor pressure at the operating temperature range of hot cathode tubes. Why should the alkaline earth metals work at all to combine with gases during the operation of the devices at temperatures way below the vaporizing temperatures of these metals. There was no such problem in the Mackay device which had an ordinary tungsten filament. The ordinary tungsten filament works all right in vacuum tubes without any getter, such as potassium or magnesium.

No reason was apparent for introducing a considerable amount of carbon into the filament. The prior patent 1,244,216 stated that electron emission drops to a low value when carbon is present in excess.

An intensive investigation of the whole subject, which was not within the range of the ordinary workers skilled in the art, finally showed that the difficulty encountered in thoriated cathode devices carrying large currents of considerable voltages, was due to the incidental increase of the pressure of potassium vapor by reason of the higher temperature of the operation until sufficient positive ionization occurred to lower or destroy the electron emissivity due to thorium. It was also found that metals such as magnesium, calcium, or the like, which had too low a vapor pressure to be vaporized appreciably by the heating of the bulb incidental to normal operation nevertheless will protect the sensitive thoriated filament, which operates by virtue of a surface film of the inconceivable thinness of about one hundred millionth of an inch. When one of these metals is vaporized upon the inner surface of the bulb, the surface exposed is so much greater than the filament surface that some adsorption phenomenon appears to come into play. Whatever may be the reason, there is no doubt that the alkaline earth metals do the trick, not only in power tubes, but also in small low temperature tubes, such as radio detectors. The ease with which they may be introduced without at the same time introducing oxides, hydrates, etc., make them superior to the alkali metals.

D

It was also found that the limitation which had existed in the use of hydrocarbons was due to the decomposition of the hydrocarbon leaving hydrogen in the bulb, which caused positive ionization, and cathode bombardment with its deleterious effect. It was found in the course of this investigation that when carbon was introduced into the cathode without the incidental liberation of hydrogen or if the hydrogen was removed before operation, that the carbon in some way modified the cathode to produce a condition favorable to steady high electron emission during operation. As a result, the functioning of the cathode became more reproducible under the unavoidable variations in conditions imposed by large scale manufacturers. This effect is even now not understood. The beneficial effect of carbon upon a thoriated cathode is well observed even when carbon seems to have disappeared (for example by combination with oxides) during the manufacture of the cathode wire. Under the new conditions, the formation of a carbide instead of being harmful, became a benefit.

It was certainly not obvious from the prior patents that carbon and alkaline metal getters could be used conjointly. Even though conjoint use of these two additions is not clearly understood, it is clear that they cooperate to produce high electron emissions. Both carbon and magnesium protect the thorium film from the effect of gases. Both coact to produce a favorable condition upon the surface of the cathode for the formation of an effective thorium film upon the cathode surface. The carbon appears to act upon the impurities in the tungsten which otherwise would accumulate on the surface and interfere with the formation of the film, and the magnesium, calcium, or the like, appear to combine with water vapor and other gases which would act deleteriously upon the surface from the outside. In one sense both the carbon and alkaline earth metal are "getters." Instead of one getter as recommended in patent 1,244,217 there are two getters, neither of which are identical with the getters of patent 1,244,217.

It certainly was not obvious from the lower vapor pressure of magnesium, that magnesium would thus act in small capacity radio tubes which operate at a temperature only slightly above room temperature. The vapor pressures of the alkaline earth metals are extremely low at a range of temperatures above room temperature. Applicant's attorney has been unable to find in a reference work a determination of the vapor pressures of these metals. Their melting points as compared with the alkali metals are an indication of the low value of the vapor pressures. A few melting point values from Laudolt-Börnstein Tabellen are instructive:

		Melting Point:
Caesium	about	25 - 26° C.
Potassium	"	62 - 63° C.
Sodium	"	97 - 98° C.
Magnesium	"	650° C.
Calcium	"	803 - 806° C.
Barium	"	850°C.

The applicant hesitates to lengthen this argument unduly, by detailed discussion of the patents cited as reference, which either merely show that magnesium had been used as a chemical agent for combining with gases to produce a vacuum, or show that carbon has been an accidental impurity in a lighting filament in which thoria constitutes a core, or show that it is known to introduce carbon into a filament by heating the same in a carbonaceous vapor. Not any of these steps are claimed broadly by themselves.

It is hoped that in view of the amendment to the claims, and the above discussion, it is not necessary to take up these remote references in detail.

The Examiner's criticism as to the number of the claims has been given earnest consideration. In view of the fact that three aspects of the invention are presented, namely:

(a) a new cathode material capable of manufacture and sale independently of the device,

(b) a new electric discharge device containing this new cathode together with a new getter, and

(c) a new method of producing this device without the disadvantages of destroying the operativeness of the cathode by the formation of by-products,

it is believed that the number of claims is not excessive.

In view of the practical importance of this invention applicant should not be obliged to jeopardize his rights by the danger of being charged with estoppels in some future litigation, due to his having cancelled claims. The claims are believed to be patentable over the references cited. In view of the difficulty of fully protecting these improvements over applicant's own prior patents by a few claims, the Examiner is earnestly requested to favorably consider the claims in their present form.

Reconsideration and allowance are respectfully requested.

Respectfully submitted,

ATTORNEY FOR LANGMUIR.

C/o General Electric Co.,
Schenectady, New York.

PATENT OFFICE
DEC 12 1924
MAILED

Please find below a communication from the EXAMINER in charge of the application of

Irving Langmuir, Ser. No. 491,634, Filed August 11, 1921
ELECTRIC EMITTING CATHODES AND METHODS OF PREPARATION.

Thomas E. Robertson
Commissioner of Patents.

Responsive to amendment filed April 26, 1924.

Record is made of

HEANY 872,936 Dec. 3, 1907 250-27

Claim 14, line 3, the insertion is incomplete.

Page 11 of applicants remarks paragraph b, states as one advantage that he gets a new cathode plus a new getter. The art shows, and applicant's statement admit, that magnesium is not a "new getter". The invention lies in the form or condition of the magnesium in the tube.

Claims such as 17 are rejected as broader than the invention and as not properly defining the invention. The claim should be limited to the form, nature and source of the magnesium deposit on the inner walls of the tube. The same applies to all other claims on magnesium as a getter.

All claims such as 5 are rejected as broader than the invention. Applicant has shown that only a certain maximum of carbon content will perform the invention.

Claims such as 1 are rejected as misdescriptive in view of lines 3 and 4 "thorium-----carbon". Thoriated cathode is suggested.

What is the cooperative relation between the thoriated cathode and the magnesium film? Does the magnesium act as a general getter agent, or more specifically as a getter for deleterious gases for example gaseous by-products from the reduction, or does it do both.

Attention is called to Heany cited, page 2 lines 122-124, and page 3, lines 100-105.

Applicant is urged to respond promptly in view of the long pendency of the case.

PATENT OFFICE
DEC 30 1924
DIV. 51 FILED

C

Honorable Commissioner of Patents,

Sir:-

In response to the Office Action of December 12, 1924, please amend the above-entitled application as follows:

Page 1, line 9, after "cathode" insert - of the type -.

Line 16, after "an addition of" insert ~~a~~ - a material capable of increasing the electron emissivity of the cathode, such for example as ~~a~~

√C¹ copied √

Page 2, line 1, cancel "thoriated" and insert after "cathode" - of the thoriated type -.

Page 5, line 30, cancel "walls" and substitute - inner surface -.

Page 6, line 25, Indicate that the matter beginning with "As explained.." should form a new paragraph.

Cancel claims 1 and 2 and rewrite as follows:

Pers C²

1. In an electron discharge device, a ~~A~~ cathode body of the thoriated type containing carbon in an amount insufficient to convert all of the metallic constituents of said cathode to a carbide but sufficient to render said cathode less sensitive to the deleterious effect of gases than a cathode body unprovided with carbon.

2. In an electron discharge device, a ~~A~~ tungsten cathode of the thoriated type adapted to emit electrons when heated, containing carbon in an appreciable amount~~s~~ but less than three per

cent by weight.

Claim 4, line 2, after "electrode" insert -- of the thoriated type --.

Lines 2 and 3, cancel "operable at incandescence and comprising a refractory metal and thoria".

Line 5, after "carbide" cancel "and".

Claim 5, line 4, cancel the comma after "carbon" and insert -- in an amount insufficient to convert said metal to a carbide, --

C3

Line 5, cancel "oxygenous" and substitute -- deleterious --.

Cancel claim 6, and rewrite as follows:

4 6. An electric discharge device comprising an envelope, an anode and a cathode of the thoriated type and a non-volatile material, which is capable of reducing thorium oxide, contained in said cathode in such small amounts that the durability of said cathode is not appreciably decreased.

Claim 7, line 3, after "tungsten" cancel the period and add the following -- in an amount materially less than required to convert all the tungsten to a carbide. --

5

Cancel claims 8 and 9 and rewrite as follows:

6 8. The method of increasing the electron emissivity of a cathode of the thoriated type which consists in introducing carbon into said cathode in an amount less than about one per cent by weight, heating said cathode in a non-carbonising and non-oxidising environment to a temperature at which a carbide of said metal is formed, activating said electrode by heating to about 2200° K. and operating the same under such conditions that bombardment of the electrode by positive ions is inappreciable.

(over)

9. The method of increasing the electron-emissivity of a cathode of the thoriated type which consists in introducing carbon into said electrode in an amount less than one per cent by weight, mounting said electrode in a bulb, evacuating the same, volatilizing magnesium in said bulb after evacuation, and activating said cathode by heating to an elevated temperature. cf. 10 [illegible]

Claim 10, lines 5 and 6, cancel "thereupon".

Line 5 after "vapor" remove the comma and

C7 insert / before the amount of carbon introduced into the filament exceeds one per cent /.

Claim 11, line 5, after "occurs," insert / by the

C8 introduction of carbon, discontinuing the heating before the tungsten has been largely converted to a carbide /.

Cancel claims 12, 13, and 14 and rewrite as follows:

C9 12. An electrical discharge device comprising a sealed envelope, electrodes therein which include a cathode of the thoriated type and a substance, having a marked chemical affinity for water vapor, deposited as a film of extensive surface upon the inside of said envelope ~~exposed to said cathode~~, said substance having a materially lower vapor pressure than the alkali metals.

13. An electrical discharge device comprising a sealed envelope, electrodes therein one of which is of the thoriated type and a film of magnesium deposited on the inner surface of said envelope.

14. An electron discharge device containing a cathode of the thoriated type, said cathode being provided with a reducing agent sufficient in quantity to promote ~~secure~~ activation of said cathode ~~during use~~, but restricted to an amount which will permit operation

D/136

of said cathode at a temperature of effective electron-emission with a commercially long life. Cl. 15-25

Claim 15, line 1, cancel "material" and substitute - of the thoriated type -.

Line 2, after "devices" insert - containing -; cancel the matter beginning with "comprising" and ending with "said material, and".

Claim 18, line 6, after "deposited" insert - as a film -.

Claim 19, line 6, after "deposited" insert - as a film on the inner surface of -; cancel "in".

Claim 20, line 6, after "deposited" insert - as a film -.

Claim 22, line 7, after "metal" insert - deposited from the vapor state in a vacuum -.

REMARKS.

The claims have been amended along the lines indicated by the Examiner. When magnesium has been used heretofore to combine with gases, it has acted in the vapor state. In the present case a film of solid magnesium (or its equivalent) guards against deterioration of a cathode extraordinarily sensitive to gases even at the extremely low pressure to be found in electron discharge devices in which ionization is absent. Even when a thoriated cathode is used in a discharge tube which has been baked out and highly evacuated, provision must be made to protect the film of thorium one atom deep on the cathode from minute amounts of gas given off during the operation of the device. It certainly is not obvious that a film of non-volatile metal will do this. Magnesium at room temperature has no appreciable vapor pressure but nevertheless is effective by reason of the large surface of the film.

Carbon in the cathode in some way also acts to give the cathode a commercially long life. It is difficult to determine exactly what the carbon does in the cathode. Its benefits are real but the conditions are such that the modus operandi is obscure.

Rather than resort to speculation applicant must say that he can not say whether or not coaction occurs between the carbon and the magnesium or other getter film. Both kinds of getter (if this term is permissible) act to preserve and render efficient the cathode as a low temperature electron emitter. Each may do so in its own way. As the Examiner no doubt is aware this invention has gone into extensive use in radio receiver tubes. It is being utilized also in power transmission devices.

An allowance is solicited.

Respectfully submitted,

Alexander D. Lunt
Attorney for Langmuir.

Serial No. 491,634

Gr
Div. 51

DEPARTMENT OF THE INTERIOR
UNITED STATES PATENT OFFICE

WASHINGTON February 5, 1925.

Irving Langmuir, Assor. to General Electric Company, a corp of New York.

Sir: Your APPLICATION for a patent for an IMPROVEMENT in ELECTRON EMITTING CATHODES AND METHODS OF PREPARATION filed August 11, 1921 , has been examined and ALLOWED.(25 claims)

The final fee, TWENTY DOLLARS, must be paid not later than SIX MONTHS from the date of this present notice of allowance. If the final fee be not paid within that period, the patent on this application will be withheld, unless renewed with an additional fee of $20, under the provisions of Section 4897, Revised Statutes.

The office delivers patents upon the day of their date, and on which their term begins to run. The printing, photolithographing, and engrossing of the several patent parts, preparatory to final signing and sealing, will require about four weeks, and such work will not be undertaken until after payment of the necessary fee.

When you send the final fee you will also send, DISTINCTLY AND PLAINLY WRITTEN, the name of the INVENTOR, TITLE OF INVENTION, AND SERIAL NUMBER AS ABOVE GIVEN, DATE OF ALLOWANCE (which is the date of this circular), DATE OF FILING, and, if assigned, the NAMES OF THE ASSIGNEES.

If you desire to have the patent issue to ASSIGNEES, an assignment containing a REQUEST to that effect, together with the FEE for recording the same, must be filed in this office on or before the date of payment of final fee.

After issue of the patent uncertified copies of the drawings and specifications may be purchased at the price of TEN CENTS EACH. The money should accompany the order. Postage stamps will not be received.

Final fees will NOT be received from other than the applicant, his assignee or attorney, or a party in interest as shown by the records of the Patent Office.

Respectfully.

Thomas E. Robertson

Commissioner of Patents.

Alexander D. Lunt
C/o General Electric Co.,
Schenectady, New York.

IN REMITTING THE FINAL FEE GIVE THE SERIAL NUMBER AT THE HEAD OF THIS NOTICE.

UNCERTIFIED ORDERS WILL NOT BE ACCEPTED.

AMENDMENT UNDER RULE 78

Honorable Commissioner of Patents,
Washington, D. C.

Sir:

It is requested that the following changes shall be made in the above application without withdrawing the same from issue.

Page 1, line 6, and wherever it appears in the title of application, change the word "CATHODE" in the title to--DEVICE--.

Line 29, before "admission" insert--beneficial results obtained by the--.

Page 2, line 12, indicate that the sentence beginning with, "In accordance" constitutes a paragraph.

In line 2 of the paragraph inserted line 16, page 2, place a comma (,) after "is".

Page 2, line 22, before "apparatus" cancel "the" and substitute,--an--.

Page 3, line 13, before "receptacle" cancel "a" and insert --the--.

Line 16, change "6" to--7--.

Page 4, line 2, cancel "and was found" and insert--sufficient--.

Page 5, line 4, cancel "method" and substitute--cathode at--.

Line 5, before "vapors" insert--the--.

Page 5, line 8, cancel the sign " % " and substitute--of one per cent,--.

Line 23, after "example" change "and" to read--an--.

Line 28, cancel "When" and substitute--By--.

Line 29, cancel "by" and substitute--with--.

Page 6, line 2, before "volatilize" insert--to--.

Line 9, place a comma (,) after "bulb".

Line 10, place a comma (,) after "operation".

Line 18, before "cathode" change "a" to--the--.

Line 21, before "carbon" insert--the--.

Line 30, before "forming" insert, --activating or--and place quotation marks before and after "forming".

Claim 1, line 1, cancel "A" and insert, --In an electron discharge device, a--.

Claim 2, line 1, cancel "A" and insert, --In an electron discharge device, a--.

Line 3, after "in" insert, --an--; same line change "amounts" to--amount--.

Claim 7, line 2, cancel "containing".

Claim 12, line 3, place a comma (,) after "substance".

Line 4, place a comma (,) after "vapor".

Line 6, cancel "exposed to said cathode".

Claim 14, line 4, cancel "permit" and substitute,--promote--; same line cancel "during use".

Claim 20, line 5, cancel "and" and substitute--together with--; same line place a comma (,) after "agent".

Line 6, place a comma after "metal" and insert--the latter being--.

Claim 22, line 7, after "which" insert--metal--.

REMARKS

The above changes are requested to correct minor errors in language and to render clear possible obscurities in terminology. None of the changes or additions involve new matter.

Respectfully submitted,

Alexander D. Lunt

Attorney for Langmuir.

Letters Patent

IN THE UNITED STATES PATENT OFFICE.

In re Letters Patent of
Irving Langmuir,
No. 1,529,597,
March 10, 1925.

ELECTRON-EMITTING DEVICES AND METHODS OF PREPARATION.

Hon. Commissioner of Patents,

Sir:-

On March 10, 1925, Letters Patent No. 1,529,597 for Electron-Emitting Devices and Methods of Preparation were granted to General Electric Company as assignee of Irving Langmuir on an application filed August 11, 1921, Serial No. 491,634. A comparison of the specification of the Letters Patent with the application file in the archives of the Patent Office shows that a certain mistake was made by said Office in printing the specification. The following correction is necessary to make the specification correspond with the file of said application:

Page 1, line 99, "what diagrammatically. An apparatus used" should be changed to read – what diagrammatically, an apparatus used –.

In accordance with the provisions of Rule 170 of Office Practice, it is respectfully requested that a certificate setting forth the above correction be duly endorsed upon the Letters Patent, and recorded in the records of patents, and a printed copy thereof attached to each printed copy of the specification and drawings.

Letters Patent No. 1,529,597 are transmitted herewith.

Respectfully submitted,

Alexander

Attorney for Langmuir.

Schenectady, N. Y.,
March 23, 1925.

Patented Mar. 10, 1925. **1,529,597**

UNITED STATES PATENT OFFICE.

IRVING LANGMUIR, OF SCHENECTADY, NEW YORK, ASSIGNOR TO GENERAL ELECTRIC COMPANY, A CORPORATION OF NEW YORK.

ELECTRON-EMITTING DEVICE AND METHOD OF PREPARATION.

Application filed August 11, 1921. Serial No. 491,604.

To all whom it may concern:

Be it known that I, IRVING LANGMUIR, a citizen of the United States, residing at Schenectady, in the county of Schenectady, State of New York, have invented certain new and useful Improvements in Electron-Emitting Devices and Methods of Preparation, of which the following is a specification.

This invention comprises an improvement in the electron emitting cathodes of the type described in my prior U. S. Patents Nos. 1,244,216 and 1,244,217.

In these patents I have described the preparation and advantages of a vacuum tube containing a cathode adapted to be operated at incandescence and containing distributed throughout its mass thorium (or a compound of thorium) as a constituent. This type of electrode consists of a refractory conducting material, such for example as tungsten, with an addition of a material capable of increasing the electron emissivity of the cathode, such for example as thoria, the latter being subjected to modifications during the preparation of the cathode in the electron discharge device so that the active material in a finished device according to all indications, consists of metallic thorium or at least of a lower oxide of thorium than thoria (ThO_2). The cathode prepared according to the methods set forth in my first Patent 1,244,216 which is commonly known as a "thoriated cathode", is very sensitive to traces of oxidizing gas in the bulb, as for example, small traces of water vapor which may be given off from the walls of the bulb during the normal operation of the device. In order to prevent loss of activity of the cathode, I have described in my second Patent No. 1,244,217, the beneficial results obtained by the admission to the bulb of a small amount of alkali metal, such as potassium or sodium, or of a hydrocarbon compound.

My present invention in one of its aspects is based on the discovery that carbon in a cathode of the thoriated type, when present in a definitely limited amount, will prevent not only reoxidation of active thorium material but what is more important, will act beneficially to reduce thoria to the active state. Although the thoriated cathodes described in my prior patents can be used with satisfactory results, I have found that a further improvement in regularity and stability can be effected by using carbon as hereinafter described, not only as in accordance with my prior patent in restricted quantities, as an oxidation preventing agent, but, as hereinafter described, as an ingredient of a thoriated cathode.

In accordance with another feature of my invention my improved cathode is used in conjunction with a non-carbonaceous reducing agent which is provided in the bulb, as for example, a highly oxidizable metal.

A thoriated cathode may be deleteriously affected by positive ion bombardment, that is, when voltages materially higher than the ionization voltages are impressed between a thoriated cathode and a positive electrode in the presence of ionizable gas, then the beneficial effect of the thorium may be largely or entirely destroyed by positive ion bombardment. Although the alkali metals are entirely satisfactory as agents to remove deleterious gases when the operating temperature of the bulb is only moderately above room temperature, as in the case of radio receiving tubes, these alkali metals have a sufficiently high vapor pressure at the operating temperature of power devices in which cathodes of the thoriated type are used to become ionized at higher voltages and to cause removal of the active film of thorium from the cathode by bombardment. I have found that it is advantageous in many cases to provide a device containing a cathode of the thoriated type with a material having an affinity for gases, such as magnesium, for example, which at the operating temperature of the device has substantially no vapor pressure. My invention will be pointed out with greater particularity in the accompanying claims and described fully in conjunction with the accompanying drawing which shows somewhat diagrammatically. An apparatus used for carrying out the preparation of an incandescent cathode rectifier.

The rectifier shown in the figure is illustrative of one of the various forms of incandescent cathode devices. It consists of a bulb 1 containing a filamentary cathode 2 into which thoria has been introduced as described in my above mentioned prior patents, and an anode 3, consisting of tungsten, molybdenum or other suitable material. These electrodes are respectively connected to lead wires 4, 4′ and 5 sealed into the walls of the bulb. The bulb is connected to the usual pumping system by means of a tubulature 6. The bulb also communicates with an elongated tube 7 adapted to be surrounded by a freezing mixture contained within a double-walled receptacle 8.

In carrying out my invention, the bulb 1 is first baked out as usual to remove water vapor and is then exhausted. Within the tube 7 is placed a substance adapted to give a low pressure of carbonaceous vapor, as for example, anthracene ($C_{14}H_{10}$) or naphthalene ($C_{10}H_8$).

When the vapor pressure of the substance employed is relatively high, I prefer to reduce the pressure of the hydrocarbon vapor in the bulb 1 by surrounding the tube with a freezing agent contained in the receptacle 8. When employing naphthalene, which has a moderately high vapor pressure, I prefer to reduce the temperature of the containing tube 7 to about −20 to −30° C. to reduce the vapor pressure to about 0.1 to 0.01 microns. The bulb 1 which communicates with the side tube 7, therefore, is filled with hydrocarbon vapor at approximately this pressure. The quantity of hydrocarbon may be controlled by one or more constrictions, such as 9, 10 which may regulate the pressure with or without a freezing agent.

The filament 2, which preferably consists of metallic tungsten, containing about ¾% thoria, is heated to a temperature of about 2300° K. (2000° C.) for a few minutes, in contact with the hydrocarbon vapor. At this temperature the incandescent filament decomposes the hydrocarbon vapor which comes in contact with the incandescent surface of the tungsten and causes the chemical combination with the tungsten of the carbon set free from the naphthalene vapor, with the formation of tungsten carbide (W_2C). The heating is continued for a length of time sufficient to give an increase in resistance of about 15 to 25% of the tungsten filament when cold, or at room temperature. This change in resistance corresponds to the presence of about two-thirds per cent of carbon by weight in the filament.

The carbon content most beneficial will vary with the conditions. In the case of a thoriated tungsten cathode all of the metallic tungsten will be converted to brittle tungsten carbide (W_2C) with a carbon content as high as 3%. Ordinarily a carbon content as high as about 1% is as high as permissible without unduly weakening the cathode. Although the presence of even minute amounts of carbon is highly undesirable in an incandescent lamp, a commercially long life can be obtained in a thoriated cathode containing carbon, as the cathode need be operated only at a relatively low temperature, say at about the operating temperature of an ordinary carbon lamp, the electron emissivity of a thoriated cathode being so much greater than that of an ordinary pure tungsten cathode. The hydrocarbon vapor is removed from contact with the filament either by sealing off the tube 7 at the contraction 9 or cooling the side tube 7 by means of liquid air in the receptacle 8 to a temperature so low that the vapor pressure of the naphthalene is negligible, thereby removing the naphthalene vapor from the bulb 1.

In some cases carbon to a desired proportion may be combined with the cathode prior to the introduction of the cathode into the bulb 1. For example, a thoriated filament may be prepared by squirting tungsten and thoria with a carbonaceous binder in amounts adapted to leave a suitable restricted proportion of carbon in the finished product.

As the next step in the preparation of the device, the anode 3 is deprived of gases by the usual method of electron bombardment; that is, by passing a discharge between the cathode at incandescence and the anode, the exhaust pump in the meantime being operated to remove the vapors and gases which are liberated. During this step some of the carbon is removed by oxidation and evaporation from the cathode but with an original carbon content of about ⅔ of one per cent enough carbon remains subsequently to furnish a supply of active thorium material by reduction of the thoria.

After the cathode has been provided with a content of reducing agent a non-carbonaceous material capable of combining with water vapor and other deleterious gases may be introduced into the bulb. In some cases this non-carbonaceous reducing agent may consist of alkali metal, such as sodium or potassium. Cæsium may be used to advantage in some cases, especially when some positive ionization is desired in the electron discharge device. Cæsium can be conveniently provided by adding a mixture of cæsium halide and metallic calcium as a paste to some part of the bulb, this method of introducing an alkali metal being claimed in an application, Serial No. 608,311, December 21, 1922, by Ernest E. Charlton.

When not desiring ionization of residual gases or vapors, I prefer to introduce for the reasons given above a reagent having a lower vapor pressure than the alkali metals, as for example, an alkaline earth metal such as magnesium, calcium, strontium, or the like. Conveniently this is done by providing within the bulb a small heating coil 11, consisting of tungsten or other suitable refractory material, and containing a small quantity of the metal to be vaporized. Preferably I employ metallic magnesium. By heating the tungsten filament 11 with current conducted thru the lead wires 4, 12, some of the magnesium is volatilized and deposited on the inner surface of the bulb which is then sealed off at the contraction 10. As during the sealing off process there is a tendency to drive out a small quantity of gas from the heated glass, I prefer to heat up the filament 11 the second time, to volatilize a small additional quantity of magnesium, or the like, in order to combine chemically with what little gas may have gotten into the bulb during the sealing off operation.

The film of magnesium, or other equivalent metal, on the walls of the bulb will combine with any water vapor or oxygen which may be given off by the bulb, or any other parts of the device during its operation, and thereby prevent an oxidization of the active thorium material upon the surface of the cathode.

The tungsten cathode 2 is preferably heated for a very short time to about 2700° K. to volatilize any thorium oxide on its surface.

As a final step, the cathode is "activated", that is, brought into its highly active state by heating to a temperature of about 2200° K. for a few minutes. This results in the reduction of thoria by the carbon and causes the active thorium product to come to the surface of the cathode where it will be effective in increasing the electron emission during the operation of the device. The tube is then ready for operation.

As explained in my prior patents, a temperature materially higher than the activating temperature will result in the thorium being volatilized from the surface of the cathode. A fresh supply can be produced and caused to accumulate upon the surface by again activating or "forming" an electrode at about 2200° K. During normal operation, the cathode is heated to a temperature below about 2200° K. and as high as 2100° K. Under these conditions, the electron emission stays constant.

What I claim as new and desire to secure by Letters Patent of the United States, is:—

1. In an electron discharge device, a cathode body of the thoriated type containing carbon in an amount insufficient to convert all of the metallic constituents of said cathode to a carbide but sufficient to render said cathode less sensitive to the deleterious effect of gases than a cathode body unprovided with carbon.

2. In an electron discharge device, a tungsten cathode of the thoriated type adapted to emit electrons when heated, containing carbon in an appreciable amount but less than three per cent by weight.

3. A cathode adapted to emit electrons at incandescence comprising tungsten, about three-quarters per cent thoria and about two-thirds per cent by weight of carbon.

4. The method of increasing the electron emissivity of an electrode of the thoriated type which consists in introducing carbon into said electrode in amounts insufficient to convert said metal to a carbide, sealing said electrode into a space substantially free from carbonaceous vapors and thereupon activating said electrode.

5. An electric discharge device comprising an evacuated envelope, electrodes therein one of which comprises a refractory metal, thorium oxide and carbon in an amount insufficient to convert said metal to a carbide, and a non-carbonaceous reagent capable of combining with deleterious gases in said envelope.

6. An electric discharge device comprising an envelope, an anode and a cathode of the thoriated type and a non-volatile material, which is capable of reducing thorium oxide, contained in said cathode in such small amounts that the durability of said cathode is not appreciably decreased.

7. An electric discharge device having a cathode comprising metallic tungsten, thorium oxide and carbon combined with said tungsten in an amount materially less than required to convert all the tungsten to a carbide.

8. The method of increasing the electron emissivity of a cathode of the thoriated type which consists in introducing carbon into said cathode in an amount less than about one per cent by weight, heating said cathode in a non-carbonizing and non-oxidizing environment to a temperature at which a carbide of said metal is formed, activating said electrode by heating to about 2200° K. and operating the same under such conditions that bombardment of the electrode by positive ions is inappreciable.

9. The method of increasing the electron-emissivity of a cathode of the thoriated type which consists in introducing carbon into said electrode in an amount less than one per cent by weight, mounting said electrode in a bulb, evacuating the same, volatilizing magnesium in said bulb after evacuation, and activating said cathode by heating to an elevated temperature.

10. The method of preparing an electrode adapted to emit electrons at incandescence which consists in heating a conductor comprising refractory metal and thoria in a carbonaceous vapor to a temperature adapted to cause combination of carbon with said conductor, removing said vapor before the amount of carbon introduced into the filament exceeds one per cent, and heating said conductor in a non-oxidizing environment to a temperature at which electron emissivity is markedly increased.

11. The method of preparing an electrode adapted to emit electrons at incandescence which consists in heating to incandescence a conductor comprising tungsten and thoria in a carbonaceous vapor until a marked increase in cold resistance occurs by the introduction of carbon, discontinuing the heating before the tungsten has been largely converted to a carbide, and heating said conductor in the absence of said vapor in a reducing environment to produce a surface layer of thorium material having a markedly higher electron emissivity than the original conductor.

12. An electrical discharge device comprising a sealed envelope, electrodes therein which include a cathode of the thoriated type and a substance, having a marked chemical affinity for water vapor, deposited as a film of extensive surface upon the inside of said envelope, said substance having a materially lower vapor pressure than the alkali metals.

13. An electrical discharge device comprising a sealed envelope, electrodes therein one of which is of the thoriated type and a film of magnesium deposited on the inner surface of said envelope.

14. An electron discharge device containing a cathode of the thoriated type, said cathode being provided with a reducing agent sufficient in quantity to promote activation of said cathode, but restricted to an amount which will permit operation of said cathode at a temperature of effective electron emission with a commercially long life.

15. A cathode of the thoriated type for electric discharge devices containing less than about three per cent by weight of carbon.

16. An electric discharge device comprising an envelope, electrodes therein one of which comprises a refractory metal, a material reducible by carbon to a state of higher electron emissivity than said refractory metal at a given temperature, and a quantity of carbon in an amount insufficient to convert said metal completely to a carbide.

17. An electrical discharge device comprising a container, electrodes therein one of which contains less than three per cent of carbon combined therewith and a material capable of materially higher electron emissivity at a given temperature than the main constituent of said electrode, but being sensitive to positive ion bombardment, and a quantity of alkaline earth metal deposited in said container out of immediate contact with said electrodes.

18. An electrical discharge device comprising a container, electrodes therein one of which contains a material capable of materially higher electron emissivity at a given temperature than the main constituent of said electrode, but being sensitive to positive ion bombardment, and a quantity of alkaline earth metal deposited as a film on the inner surface of said container.

19. An electrical discharge device comprising a container, electrodes therein one of which contains a material capable of materially higher electron emissivity at a given temperature than the main constituent of said electrode, but being sensitive to positive ion bombardment, and a quantity of magnesium deposited as a film on the inner surface of said container out of immediate contact with said electrodes.

20. An electrical discharge device comprising a container, electrodes therein one of which consists largely of refractory metal and contains an oxide of a metal of high electron emissivity which when rendered active is sensitive to ion bombardment together with a reducing agent, and a quantity of alkaline earth metal, the latter being deposited as a film on the inner wall of said container.

21. An electrical discharge device comprising a glass bulb, electrodes therein one of which consists largely of refractory metal and contains a material capable when activated of substantially increasing the electron emission of the electrode with which it is associated but which is deteriorated by oxidation and positive bombardment, and a film of magnesium coating the inner surface of said bulb.

22. An electrical discharge device comprising a container, electrodes therein, one of which contains as a constituent a material capable of higher electron emission than the main constituent of said electrode but which is sensitive to positive ion bombardment, and to the chemical effect of water vapor under operating conditions, and a film of metal deposited from the vapor state in a vacuum on the wall of said container which metal has a high chemical affinity for water vapor and has a materially lower vapor pressure at the operating temperature of said device than the alkali metals.

23. The method of increasing the electron emissivity of a metallic electrode containing a compound capable upon reduction of materially increasing the electron emissivity of said electrode which consists in introducing carbon into said electrode in an amount insufficient to convert the metal constituting said electrode completely to a carbide and heating said electrode in a non-oxidizing and non-carbonizing environment to a temperature sufficiently high to activate said electrode, and thereupon operating said electrode under conditions which render the effect of positive ion bombardment of said electrode inappreciable.

24. An electrode material for an electrical discharge device consisting of a metal capable of stable operation at an elevated tem-

perature, a compound of a material capable in a reduced state of higher electron emission than said metal, and carbon in a quantity insufficient to deleteriously affect the strength of said material, but being capable of reducing a sufficient amount of said compound to enable said electrode to be more readily activated during use than would be the case in the absence of said carbon.

25. A cathode material for electrical discharge devices consisting largely of a metal capable of operation at an elevated temperature, a reducible compound of a material of high electron emissivity and less than about one per cent of carbon.

In witness whereof, I have hereunto set my hand this 8th day of August, 1921.

IRVING LANGMUIR.

Coolidge Article in "Physical Review" of December, 1913, "A Powerful Rontgen Ray Tube With a Pure Electron Discharge."

Second Series *December, 1913* *Vol. II, No. 6*

THE

PHYSICAL REVIEW.

A POWERFUL RÖNTGEN RAY TUBE WITH A PURE ELECTRON DISCHARGE.

By W. D. Coolidge.

§ 1. Introduction.

In an earlier publication attention has been called[1] to the use of wrought tungsten for the anticathode, or target, of a Röntgen tube of the ordinary type. In the development of this target many different designs were made and mounted in tubes, and these tubes were operated on what was then the most powerful Röntgen apparatus on the market, a 10 K.W. transformer coupled to a mechanical rectifying device. The operation of tubes in this manner, to see how much energy it took to ruin the target, gave perhaps an unusual viewpoint. When, as a result of these experiments, a satisfactory form of target had been developed, the writer became interested in studying the remaining limitations in the tube. Some of these limitations are the following:

1. With low discharge currents the vacuum gradually improves, with a consequent increase in the penetrating power of the rays produced.

2. With high discharge currents there are very rapid vacuum changes, sometimes in one direction and sometimes in the other.

3. If a heavy discharge current is continued for more than a few seconds the target is heated to redness and then gives off so much gas that the tube may have to be reëxhausted.

4. If the temperature of the standard copper-backed target is allowed to get up to bright redness, a rapid deposition of metallic copper begins to take place on the bulb, continuing for some time after the cutting off of the current, owing to the very slow rate of cooling from such temperatures in the evacuated space.

5. Of the tubes tested, very many have failed from cracking of the

---

[1] Coolidge, Trans. Am. Inst. E. E., June, 1912, pp. 870–872.

glass, and this, with one exception, always at the same point; that is, in the zone around the cathode. In many cases there has first been chipping-out of the glass from the inner surface of the tube at this point.

6. The focal spot on the target in many tubes wanders about very rapidly.[1] In many cases where it does not show a tendency to wander, it will be found after a heavy discharge to have permanently changed its location.

7. While it is relatively easy to lower the tube resistance by means of the various gas regulators, it is a relatively slow matter to raise it much.

8. With very heavy discharges, the central portion of the usual massive aluminum cathode melts, and the molten globules so formed are shot right across the tube, flattening themselves out on the glass and sticking to it. When the melted area is small, no harm is done except that the curvature of the cathode at this point may be changed, and the focal spot may, in consequence, be moved.

9. No two tubes are exactly alike in their electrical characteristics.

10. The characteristics are in general far from ideal, in that the penetrating power of the Röntgen rays produced, changes with the magnitude of the discharge current.

11. When operated on a periodically intermittent current, even though it be of constant potential, the tube, of necessity, gives a very heterogeneous bundle of primary Röntgen rays, for the reason that the breakdown voltage of the tube is much higher than the running voltage.[2]

It was found that limitations 3 and 4 could be removed by the use of a massive all-tungsten (in place of the usual copper-backed) target. Such a target can be run continuously at intense white heat. Aside from eliminating the troubles incident to the use of copper, the all-tungsten target does not change the general characteristics of the tube.

An attempt was made to remove limitation 8, imposed by the low melting point of aluminium, by substituting for it a tungsten cathode of the same dimensions. Tubes made up in this way showed a behavior entirely different from that of the ordinary tube. They would have been absolutely hopeless from the standpoint of a practical radiographer. They were like the ordinary Röntgen tube which is in the condition which the radiographer describes as "cranky." Upon passing a discharge current of any magnitude through the tube, the resistance would quickly rise to a point where, even with an impressed potential difference of 100,000 volts, no further discharge would pass. The tube could be restored to its original condition by the liberation of gas from the vacuum

---

[1] In radiographic work, movement of the focal spot during an exposure is of course detrimental to good definition.

[2] See F. Dessauer, Phys. Zeitschr., 14, pp. 246–247 (1913).

regulator. The phenomena would repeat themselves as often as one cared to make the experiment. Continuous operation for even a few seconds seemed out of the question. It finally developed, however, that with the adoption of the following expedient, the situation changed. Gas was admitted from the regulator and a discharge passed through the tube. As soon as the resistance had risen, more gas was admitted and the tube was again excited. These operations were repeated as rapidly as possible. With each excitation of the tube, the cathode became hotter. There was evidently the same focusing of the positive ions bombarding the cathode as there was of the electrons at the anticathode, for there was a similar localization of heat at the two electrodes. A little conical depression which formed at the center of the cathode showed that, with the vacuum range employed, the positive ion bombardment was, at least mainly, confined to an area only about 2 mm. in diameter. As soon as the cathode had become heated to bright incandescence,[1] the behavior of the tube changed, and it could then be operated continuously for at least several minutes. Upon interrupting the discharge for a short time, and so allowing the cathode to cool, the "cranky" condition returned, and the tube could again be operated continuously only after repeating the procedure outlined above.

Tubes like the above with tungsten cathodes showed, upon operation, a rapid blackening of the bulb. The deposit proved to be metallic tungsten. The conical depression which invariably formed at the center of the cathode seemed to indicate that this was the source of the deposit, the disintegration of the metal at this point being doubtless due to the mechanical action of the positive ions which bombard it.

The extreme instability of vacuum attendant upon the use of a tungsten cathode in what was otherwise a standard Röntgen tube, called attention very forcibly to the part which is played by gases in the ordinary aluminum cathode. (The tungsten cathodes used must have been, from their method of manufacture, relatively very free from gas.)

A consideration of the above-mentioned limitations showed that they were for the most part incident to the use of gas and that they could therefore be made to disappear if a tube could be operated with a very much higher vacuum. In this case the electrons would have to be supplied in some other way than by bombardment of the cathode by positive ions.

---

[1] The magnitude of the heating effect at the cathode was much greater with tungsten than it is with aluminum cathodes. In one case the cathode and the anode, which functioned also as anticathode, were both made of tungsten, exactly alike in size and shape and symmetrically placed in the tube (concave faces towards each other). On continuous operation, both ran at white heat, and, as nearly as the eye could judge, at the same temperature. Where aluminum is used as the cathode material, much less heat is developed in the cathode than in the target. Willey (Vernon J. Willey, Archives of the Roentgen Ray, XII., p. 250, 1908) finds in tubes of the ordinary type that 75 to 85 per cent. of the total heat evolution in the tube, inclusive of the glass walls, takes place at the target.

Richardson[1] and others had shown that electrons might be produced by simply heating the cathode. But the values of the thermionic currents obtained by different observers had varied between wide limits, so much so as to suggest that a Röntgen tube based upon this principle might be as unstable in resistance as is the standard tube. Moreover, the fact that the substances usually worked with, platinum and carbon, are so difficult to completely free from gas, suggested strongly that with the cleaner conditions (greater freedom from gas) that could be realized by the use of tungsten, the thermionic currents might cease altogether.[2] Some experiments of Dr. Irving Langmuir,[3] however, on the thermionic currents between two tungsten filaments in a highly evacuated space, were very reassuring. According to his observations, after a certain high degree of exhaustion had been reached, the thermionic currents increased, up to a certain limiting value, as the tube became freer and freer from gas.

The idea of using a hot cathode in a Röntgen tube was not new, but, so far as the writer could learn, the principle had never been successfully applied in a vacuum good enough so that positive ions did not play an essential rôle.

Wehnelt and Trenkle[4] had used a hot lime cathode for the production of very soft Röntgen rays, working with voltages from 400 to 1,000. Wehnelt, in another article, describes the use of his lime cathode in a Braun tube, and here he says that it is not advisible to employ more than 1,000 volts, as otherwise cathode rays come off from that part of the platinum which is bare, giving bad disintegration.

The Röntgen rays produced by voltages as low as 1,000 are of course too "soft" for the ordinary applications.

Lilienfeld and Rosenthal[5] had described a Röntgen tube whose penetrating power is, they say, independent of vacuum. Their main aluminum cathode and their platinum anticathode are shaped and located like the electrodes in the ordinary Röntgen tube. Besides these they have an anode and an auxiliary hot cathode. Current from a low voltage source passes from the hot cathode to the anode and this current furnishes the positive ions which by their bombardment of the main cathode liberate electrons from it. Their tube is dependent for its operation on the presence of positive ions, for without these there is no means provided for getting electrons out from the main, aluminum, cathode. Lillienfeld concludes from his extended experiments in tube exhaustion that the complete removal of all gas from tube and electrodes would not do away with positive ions. There would according to this view be no such thing as a pure electron discharge. Lilienfeld's work in exhausting the gas from the tube itself and from the glass seems to have been excellent, but according to the experience of the writer, his electrodes were not sufficiently freed from gas to justify the conclusions drawn. Working even with tungsten electrodes in a tube so designed that the electrodes could be heated in place to very high temperatures, the writer has had the positive ion effects persist for hours, disappearing completely however as the electrodes become sufficiently freed from gas.

[1] Proc. Camb. Phil. Soc., XI., 286 (1902); Proc. Roy. Soc., LXXI, pp. 415–418 (1903).

[2] See Goldstein, Ann. der Physik, 24, p. 91, 1885. He finds that platinum must be heated almost to its melting point to give an appreciable thermionic current. Also see H. A. Wilson, Proc. Roy. Soc., 72, pp. 272–276 (1903). He concludes with the following statement: "It is probable that a pure platinum wire heated in a perfect vacuum would not discharge any electricity at all, either positive or negative, to an extent appreciable on a galvanometer."

[3] This work is just being published.

[5] J. E. Lilienfeld and W. J. Rosenthal, Fortschritte auf dem Gebiete der Röntgenstrahlen, 18, 256–263 (1912).

The work of Dr. Langmuir had shown that a hot tungsten cathode in a very high vacuum could be made to continuously yield a supply of electrons at a rate determined by the temperature.

Further work showed that very high voltages, up to at least 100,000, in no wise affect this rate of emission. For application to the fields of radiography and fluoroscopy, it was necessary to develop a satisfactory method of focusing. And, finally, the large amounts of energy transformed into heat in a Röntgen tube render imperative the use of a very heavy target, and this made it necessary to develop methods for sufficiently freeing from gas large masses of metal.

The result of efforts in this direction has been entirely successful, and tubes have been made, based upon this principle, which are free from all of the above-mentioned limitations. This is of particular physical interest because it brings all of the peculiarities of the Röntgen ray tube into accord with the modern conception of electronic conduction and gas molecule decomposition. In the following, it will be sufficient to describe one type (a focusing tube) and its characteristics, leaving for later papers the description of other types.

§ 2. GENERAL DESCRIPTION OF THE NEW TYPE OF TUBE.

The structural features of the new tube which differ from those of the ordinary type are the following:

The pressure, instead of being, as in the ordinary tube, a few microns, is as low as it has been possible to make it, that is, not more than a few hundredths of a micron.

The cathode consists of a body which can be electrically heated (such as a tungsten or tantalum filament) and, suitably located with reference to this portion, an electrically conducting ring or cylinder, consisting preferably of molybdenum or tungsten or other refractory metal. The ring or cylinder is connected either to the heated portion of the cathode, or to an external source of current by means of which its potential may be brought to any desired value with respect to the heated portion. The heated portion of the cathode serves as the source of electrons, while the ring or cylinder assists in so shaping the electrical field in the neighborhood of the cathode that the desired degree of focusing of the cathode-ray stream upon the target shall result.

The anticathode, or target, functions at the same time as anode.

The operation is satisfactory only when the vacuum is exceedingly high, so high that the ordinary tube would carry no current even on 100,000 volts.

§ 3. THEORY OF OPERATION.

As will be seen from the characteristics of the tube, in § 5, it gives, in operation, no evidence of positive ions. This makes the theory of its operation exceedingly simple.

The discharge appears to be purely thermionic in character.

The rate of emission of electrons from the filament appears to be in accord with Richardson's Law, which says that the maximum thermionic current, which can be drawn from a hot filament is

$$i = a\sqrt{T}e^{-\frac{b}{T}}$$

where T is the absolute temperature, e is the base of the natural system of logarithms, and a and b are constants.

In the particular tube described in detail in this paper, over the range of temperatures and voltages included in the data of Table I., this simple law accounts perfectly for the conductivity of the tube. With still higher temperatures, however, the discharge currents would be found to increase at a much slower rate than that required by the above law. And the same applies, even in the temperature range of Table I., to a different tube design in which the distance between cathode and anode is greater. In these cases the failure to follow Richardson's Law at the higher temperatures has been accounted for by Dr. Langmuir[1] by the spacial density of negative electricity in the neighborhood of the cathode.

§ 4. DETAILED DESCRIPTION OF TUBE NO. 147.

This description relates to tube No. 147, which was used in getting the data for the following tables. Fig. 1 shows a complete assembly, while Fig. 2 shows an enlarged detail of the cathode and of the front end of the target.

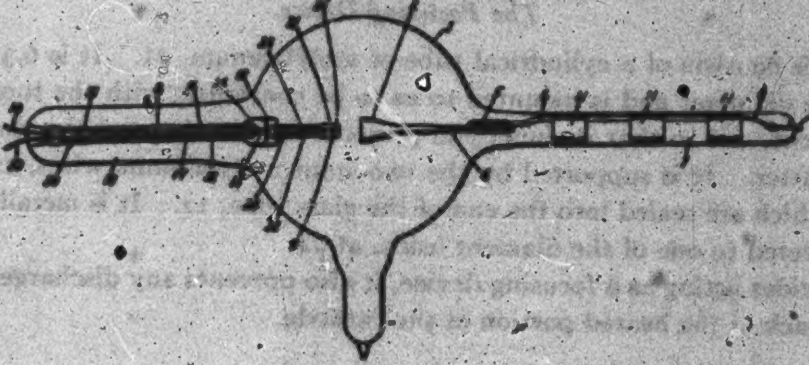

Fig. 1.

The Cathode.

In the diagrams, 25 is a tungsten filament in the shape of a flat, closely wound spiral. It consists of a wire 0.216 mm. in diameter and 33.4 mm. long with 5½ convolutions, the outermost of which has a diameter of 3.5 mm. It is electrically welded to the ends of two heavy molybdenum wires 14 and 15, to the other extremities of which are welded the two copper wires 16 and 17. These in turn are welded to the platinum wires 18 and 19. The molybdenum wires are sealed directly into a piece of special glass, 12, which has essentially the same temperature coefficient of expansion as molybdenum. This first seal is simply to insure a rigid support for the hot filament, the outer seal being the one relied upon for vacuum tightness. The outer end, 13, of the support tube is of German glass like the bulb itself, and it is therefore necessary to interpose at *S* a series of intermediate glasses to take care of the difference in expansion coefficients between 12 and 13. The small glass tube, 20, prevents short-circuiting of the copper wires, 16 and 17.

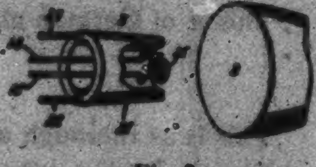

Fig. 2.

The filament is heated by current from a small storage battery which is, electrically, well insulated from the ground.

In the circuit are placed an ammeter and an adjustable rheostat and, by means of the latter, the filament current can be regulated, by very fine steps, from 3 to 5 amperes. Over this current range, the potential drop through the filament varies from 1.8 to 4.6 volts and the filament temperature from 1890 to 2540 degrees absolute.

The Focusing Device.

This consists of a cylindrical tube of molybdenum, 21. It is 6.3 mm. inside diameter and is mounted so as to be concentric with the tungsten filament, and so that its inner end projects 1.0 mm. beyond the plane of the latter. It is supported by the two stout molybdenum wires, 22 and 23, which are sealed into the end of the glass tube, 12. It is metallically connected to one of the filament leads, at 24.

Besides acting as a focusing device, it also prevents any discharge from the back of the heated portion of the cathode.

The Anticathode or Target.

The anticathode or target, 2, which also serves as anode, consists of a single piece of wrought tungsten, having at the end facing the cathode a diameter of 1.9 cm. (Its weight is about 100 gm.) By means of a molybdenum wire, 5, it is firmly bound to the molybdenum support, 6. This support is made up of a rectangular strip and, riveted to this, three split rings, 11, 11, 11, all of molybdenum. The split rings fit snugly in the glass anode arm, 7. They serve the double purpose of properly supporting the anode and of conducting heat away from the rectangular strip and so preventing too much heat flow to the seal of the lead-in-wire, 9.

The Bulb.

This is of German glass and about 18 cm. in diameter.

The Exhaust.

This is as thorough as possible.

For the earlier tubes, mercury pumps were used, with a liquid-air trap between tube and pump to eliminate mercury vapor. The whole tube, while connected to the pump, was in an oven and was heated at intervals to 470° C. Between heating operations the tube was operated with as heavy discharge currents as the condition of its vacuum would permit. For hours the tube would show the characteristics of an ordinary Röntgen tube, and in many cases a several days' application of the above treatment was required to entirely eliminate these characteristics and to realize an essentially pure electron discharge.

The exhaust time has been greatly reduced in two ways. The massive tungsten anode is given a preliminary firing to a very high temperature in a tungsten-tube vacuum furnace.[1] The molybdenum support is also fired, to a somewhat lower temperature, in the same manner. In the second place, a Gaede molecular pump has been substituted for the mercury pumps and, at the same time, a very large and short connection has been adopted between tube and pump.

In the later stages of the exhaust a very heavy discharge current is maintained continuously on the tube for perhaps an hour, the temperature of the bulb being kept from rising too high by the use of a fan.

The pressure in the finished tube is very low, certainly not more than a few hundredths of a micron and probably much less than this.

Connections and Method of Operating.

The tube was connected as shown in the diagram, Fig. 3, in which, *T* is the tube; *B* is a small storage battery; *A* is an ammeter; *R* is an adjustable rheostat which can be controlled from behind the lead screen which shields the operator from the Röntgen rays; *S* is an adjustable spark gap with pointed electrodes, which can also be operated from behind

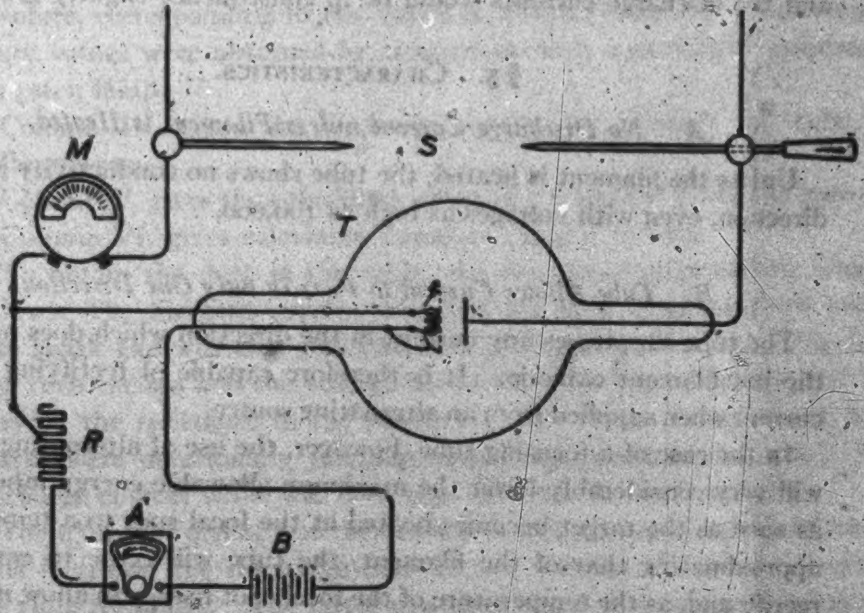

Fig. 3.

---

[1] A description of this furnace will be published in the near future. The heating element consists of a tungsten tube 2.5 cm. inside diameter and 30 cm. long. This is fastened in an upright position and, by means of suitable terminals, is connected to a 100 K.W. transformer. The heating element is placed in a water-cooled metal cylinder and the space within connected to a pump which maintains, with the furnace at its highest temperature, a vacuum of a few microns.

the lead screen; and *M* is a milliampere-meter which can be read from behind the screen.

As the high potential is connected to the battery circuit it is necessary that the latter shall be thoroughly insulated from the ground.

As a high potential source, a 10 K.W. Snook machine, made by the Röntgen Apparatus Co., was used. This consists of a rotary converter driven from the direct current end and delivering alternating current at 130 volts and 60 cycles per second to a closed magnetic circuit step-up transformer with oil insulation. From the secondary of this transformer the high voltage current is passed through a mechanical rectifying switch (which is direct-connected to the shaft of the rotary) and the milliampere-meter, *M*, to the tube. The output of the transformer is controlled by a variable resistance in the primary.

Throughout these experiments a fan was kept blowing on the tube. Without this fan, the gas pressures in the tube would be slightly higher, and the discharge currents would be in consequence slightly lower.

§ 5. CHARACTERISTICS.

A. *No Discharge Current unless Filament is Heated.*

Unless the filament is heated, the tube shows no conductivity in either direction, even with voltages as high as 100,000.

B. *Tube Allows Current to Pass in only One Direction.*

The tube suppresses any current in the direction which does not make the hot filament cathode. It is therefore capable of rectifying its own current when supplied from an alternating source.

In the case of a focusing tube, however, the use of alternating current will very considerably lower the maximum allowable energy input. For as soon as the target becomes heated at the focal spot to a temperature approximating that of the filament, the tube will cease to completely rectify and, as the temperature of the focal spot rises, will allow more and more current to pass in the wrong direction. This, to be sure, will not cause either a harmful vacuum change or a metallic deposit on the bulb, as it would in the case of the ordinary tube; but it will give rise to needless heating of the bulb where it is bombarded by the cathode rays from the target, and to disturbing Röntgen rays emanating from the glass at this point. In the case of a tube which does not focus, but in which the cathode rays bombard the entire surface of the anode, the allowable energy input which the tube will completely rectify can be increased to any desired amount by simply increasing the surface of the anode.

C. *Discharge Current Determined Primarily by Filament Temperature.*

With a given design, the amount of discharge current which can be passed through the tube is determined primarily by the temperature of the filament, and responds instantly to changes in the same in either direction.

The effect of both temperature and voltage on the discharge current, in the case of tube No. 147, illustrated in Fig. 1, may be seen by referring to Table I., which gives the data on the finished tube after it had been sealed off from the pump. The focal spot was 3 mm. in diameter.

In the table, Column I. gives the length in centimeters of the equivalent spark gap.

Column II. gives the heating current (*C*) in the filament, expressed in amperes.

Column III. gives the filament temperature (*T*), expressed in degrees absolute, corresponding to the values of *C* in Column II. The temperature values were obtained by comparison with a previously calibrated tungsten lamp.

Column IV. gives the discharge current (*i*) through the tube, in milliamperes.

Column V. gives the calculated values of $(-\log i/\sqrt{T})$ to the base 10.

Column VI. gives calculated values of $(.434/T \times 10^5)$.

To obtain the data in the table, the experimental procedure was as follows: The filament current was first set at a predetermined point. The spark gap was next set, also at a predetermined point. The tube was then excited and the voltage across the tube terminals adjusted (by varying the resistance in the primary circuit of the transformer) until sparks were occasionally jumping across the parallel spark gap. The discharge current value was then read off from the milliammeter.

The filament current was then raised to a second predetermined value. This increased the discharge current and lowered the potential across the tube terminals. The latter was then raised to its original value and and the new discharge current reading was obtained.

In this way the discharge current value, for a given voltage, was brought up by steps to the point where the tube finally began to show signs of instability. The temperature-current series was then repeated with a different voltage.

The values of discharge current and temperature, for each voltage, are plotted in Fig. 4. The different curves are seen to lie very close together, showing that over the range of voltages employed, the magnitude of the discharge current is practically independent of voltage.

This shows that the current in these experiments was always the saturation value.[1]

According to Richardson, the relation between the saturation current flowing from a hot filament and the absolute temperature of the filament, is expressed by the equation $i = a\sqrt{T}e^{-\frac{b}{T}}$, in which i is the current, T is the temperature, and a and b are constants of which the first has to do with the concentration of electrons within the hot body, and the second represents the amount of work required to get the electron through the surface of the metal. e is the base of the Naperian system of logarithms.

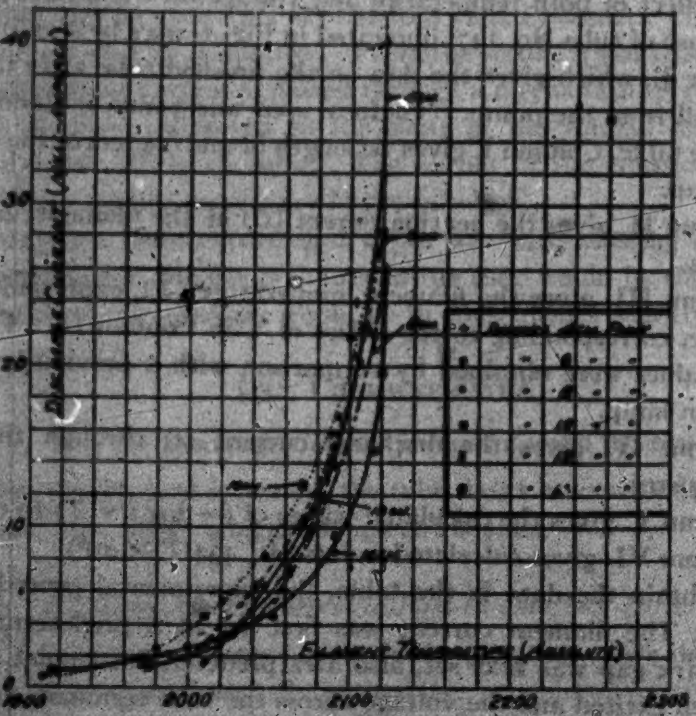

Fig. 4.

Richardson[2] applies this equation to his data by first taking the logarithm, to the base 10, of both sides of the equation, which gives

$$\log i = \log a + \tfrac{1}{2}\log T - \frac{b}{T}(.434)$$

or

$$-\log\frac{i}{\sqrt{T}} = b\,\frac{.434}{T} - \log a,$$

which is the equation of a straight line.

[1] The two points to the extreme right of the curves correspond to an unstable condition of the tube. The instability disappears instantly upon lowering the filament temperature.

If then the values of Columns IV. and V. are plotted, they should lie along straight lines, provided conduction in the tube, between the voltage limits used, follows Richardson's Law.

Reference to the plots, Figs. 5 and 6, will show that the points are closely represented by straight lines. By reading off the tangents of the angles which the lines make with the horizontal axis we get the following values of the constant *b*:

Voltage Corresponding to Spark Gap of	Value of *b*.
4 cm.	115,000
6 cm.	93,000

10 cm.	71,000
12 cm.	76,000
14 cm.	60,000
Average	85,000

These values of *b* are interesting in that they all fall within the range of the values which are just being published by Dr. Langmuir. His

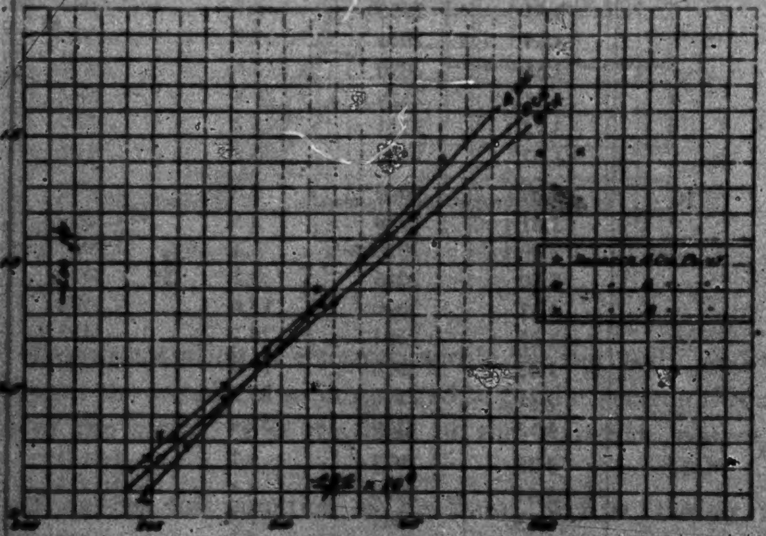

Fig. 5.

values were obtained from an apparatus in which the electrodes were fine tungsten filaments having a total mass perhaps 1/100,000 of that of the target in the above tube. His results show the enormous effect of gas on the value of *b*, and the conclusion can, therefore, be drawn, that very large tungsten masses can be used in a tube without, to any appreciable extent, impairing the vacuum, even though these masses may be heated close to their melting point.

If the temperature of the filament is low, only a small number of electrons escape from it and, consequently, only a small discharge current (the saturation current) can be sent through the tube. Increasing the impressed voltage above that needed for this current value causes no further increase in current. It simply increases the velocity of the cathode rays and hence the penetrating power of the Röntgen rays.

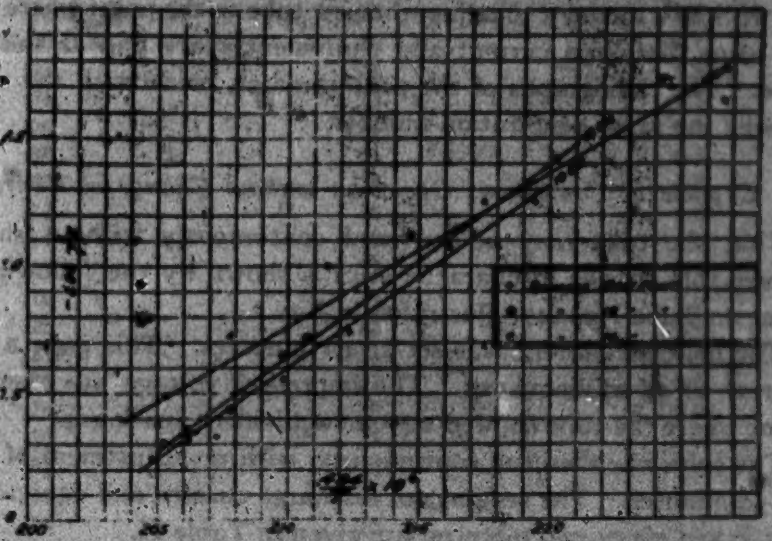

Fig. 6.

At higher filament temperatures there is a current-limiting factor, other than the number of electrons emitted by the hot filament, which plays a dominating part. This factor is the spacial density of negative electricity in front of the cathode, which amounts, in effect, to a back electromotive force. This factor would play a very important rôle at lower voltages; but in the case of the Röntgen ray tube the voltages involved are so high that, in case a suitable design is used, its influence can be entirely avoided, as is shown by the data of Table I.

D. *Penetrating Power of Röntgen Rays Determined by Voltage across Tube Terminals.*

The penetrating power of the Röntgen rays coming from the tube increases with the potential difference between tube terminals.

With the tube excited from a variable potential source, such as the transformer, it did not seem safe to predict that, with the same equivalent spark gap, the rays would show, photographically, the same penetrating power as those from a standard tube. But upon making the experiment, using a Benoist penetrometer,[1] it was found that they did.

---

[1] M. L. Benoist, C. R., 134, 225 (1902).

The experiment was interesting from another point of view in that it showed how readily the new tube could be adapted to a given set of conditions.

An exposure was made first with a standard tube of the ordinary type, and the discharge current and equivalent spark gap were noted. A tube of the new type was then set up in place of the standard. It was but the work of a moment to adjust the new tube to the point where it showed the same discharge current and equivalent spark gap as the standard tube. The radiographs of the penetrometer, made with the two tubes, showed the same penetration number.

E. Capable of Continuous Operation without Change of Characteristics.

That the tube may be operated continuously without showing an appreciable change in characteristics is shown by the following experiment on Tube No. 147, illustrated in Fig. 1.

The filament current was set at 4.1 amperes. This gave a discharge current of 25 milliamperes. The impressed voltage was then set at a point where the tube showed a 7 cm. equivalent spark gap.

The tube was then run continuously, with no adjustment of any kind, for 50 minutes. The readings of discharge current and equivalent spark gap, taken every two minutes, are given in Table II.

F. Sharpness of Focus.

Sharpness of focus is determined mainly by the design of the tube. If the filament temperature is such that, with the voltage employed, the discharge current does not represent the saturation value, the size of the focal spot will vary with the impressed voltage. But in the tube shown in Fig. 1, over the range of voltages corresponding to an equivalent spark gap ranging from 4 to 14 cm., the focal spot does not vary appreciably in size.

The tube may be made to focus more sharply by increasing the distance between the filament and the front (end facing the target) of the molybdenum tube. This change in design will also affect the temperature-current characteristics of the tube in the direction that a higher filament temperature will be needed for a given discharge current value.

Similarly it may be made to focus less sharply by decreasing the distance between the filament and the front of the focusing device.

All of the observations made are consistent with the idea that focusing is determined by the shape of the equipotential surfaces which may be drawn in the space between cathode and anode, and that the surfaces close to the cathode have the strongly preponderating influence.

TABLE II.

Near the cathode, the velocity of the electrons is relatively small, and the direction of their motion will therefore conform closely to the direction of the strong electric force. Near the anode, on the other hand, the velocity of the electrons is so high that the same force acting over the same length of path will produce but little deflection.

G. *Fixity of Position of Focal Spot.*

The focal spot on the anode does not wander, but remains perfectly fixed in position. This is in sharp contrast to the ordinary Röntgen tube in which the focal spot does move about, and often so rapidly as to be noticeable even during the shortest radiographic exposures.[1] The effect of movement of the focal spot is, of course, to cause in the radiograph or on the screen, a blurring of all lines except those parallel to the direction of motion. In the earlier stages of exhaustion, while the new tube is being operated with a relatively poor vacuum, the focal spot may dance about, but as the electrodes and the glass become freer from gas the mobility of the focal spot decreases and finally disappears completely. Its disappearance goes hand in hand with the disappearance of fluorescence of the glass, discussed in section *J*. Movement of the focal spot appears to be due to the action of positive ions in disturbing the distribution of static charge on the glass walls of the tube.

---

[1] See Dr. Pfahler, Fortschritte auf dem Gebiete der Röntgen[illegible], 18, pp. 340-343 (1911-1912).

H. Tube not Sensitive to Considerable Changes in Gas Pressure.

The gas-pressure within the tube is so low that it can increase severalfold, and apparently decrease without limit, without appreciably affecting the other characteristics.

The slight effect of pressure change may be seen from the following experiment:

While one of the tubes was being continuously operated on the pump, the pressure, as indicated by a McLeod gage, decreased from 0.113 to 0.035 micron.[1] The discharge current passing through the tube remained constant at 3.1 milliamperes, while the parallel spark gap backed up by the tube changed only from 7.9 to 8.6 cm. A corresponding pressure change in the case of an ordinary Röntgen tube would bring about an enormous change in current and voltage.

I. Capable of Continuous Operation with High Energy Input.

Owing to the fact that the tungsten target can run at such a high temperature, large amounts of energy can be continuously radiated.

J. No Fluorescence of Glass.

When operating properly the tube shows no fluorescence of the glass at any point. Corresponding to this, there is an absence of the usual strong local heating of the anterior hemisphere. The absence of fluorescence and of local heating seem to point to the fact that there is no bombardment of the glass by secondary cathode rays sent out from the target. This is in striking contradistinction to what takes place in an ordinary Röntgen tube, where, in the case of a platinum target, it has been found that there are about three-fourths as many electrons leaving the target, and going to the glass, as secondary cathode rays, as there are bombarding it, in the form of primary cathode rays. This elimination of secondary cathode ray bombardment prevents the production of a large part of the useless and disturbing Röntgen rays which emanate from the glass in the case of the ordinary tube.

The absence of bombardment of the glass is of interest both theoretically and practically. Other explanations of the lack of fluorescence suggested themselves at first. A plausible hypothesis was that bombardment took place, but that the surface of the glass was much freer from gas than it is in the ordinary tube and that this accounted for the lack of fluorescence. But the fact that fluorescence appears so suddenly when a trace of gas is evolved, coupled with the fact that such fluorescence may appear in streaks and that these may rapidly change their location, seems to disprove the hypothesis. It also seemed possible at first that the fluorescence might be there, but that it could not be seen because of the strong light emission from both filament and target. But this hypothesis is disproved by the fact that with filament and target at their highest temperatures, fluorescence becomes suddenly strongly visible whenever gas is liberated.

---

[1] In the light of later experiments it seems doubtful whether a further pressure decrease, no matter how great, would have appreciably affected the tube characteristics.

The simple explanation appears to be based upon the fact that the large number of positive ions present in an ordinary Röntgen tube is here lacking. The inner surface of the glass becomes strongly negatively charged, when the tube is first operated, and, not being able to attract an appreciable number of positive ions, remains so. The presence of this negative charge upon the glass prevents further electrons, either in the shape of primary or secondary cathode rays, from going there.

K. *Identity of Starting and Running Voltage.*

The starting, or break-down, voltage of the tube is the same as the running voltage. This is very different from the state of affairs in the ordinary tube in which the break-down voltage is much higher than the running voltage.[1] The difference is to be explained as follows: In the ordinary tube the number of ions present when the circuit is closed is exceedingly small, being only that due to natural ionization causes, such as radioactive matter in the surroundings. After the discharge circuit is closed, the number of ions increases, by collision, very rapidly, and the voltage across the tube terminals falls in consequence. In the case of the new tube, on the other hand, the full supply of electrons is there the instant the discharge circuit is closed, and even before this, and the available number is not changed by the discharge current.

L. *Permits of Realization of Homogeneous Bundle of Primary Röntgen Rays.*

The tube must permit of the realization of a strong homogeneous bundle of primary Röntgen rays of any desired penetrating power. For this purpose it should clearly be excited from a source of constant potential. The result should be attained even though the discharge is intermittent.[1]

---

[1] See Dessauer, l. c.

M. No Heating of Cathode by Discharge Current and no Evidence of Cathodic Disintegration.

An earlier experiment showed that when a tube is made up with two similar concave tungsten electrodes, symmetrically located in the tube, and operated on direct current at an ordinary Röntgen tube vacuum, the heating effect at the cathode is as strong as that at the anode. Furthermore, the heat evolution at the cathode is as strongly localized as it is at the anode. In fact, it is impossible, when the tube is operating, to tell, by looking at it, which of the white hot electrodes is functioning as anode and which as cathode. There is a very rapid blackening of the bulb in such a tube, the material of the deposit coming evidently from the cathode, which shows a deep and sharply defined cavity at the point of local heating. The simple explanation seems to be that the cathode is bombarded by positive ions and that the emission of the electrons which constitute the cathode ray stream is due to this bombardment. So, also, the heating effect and the cathodic disintegration.

At the higher vacuum and with the relatively gas-free electrodes of the new tube there is no evidence of any bombardment of the cathode. In the earlier stages of gas removal, when a discharge can be made to pass through the tube without the heating current in the filament, the latter is seen to be strongly locally heated by the discharge current, as from bombardment by positive ions. But when the exhaustion has been completed and the tube is operated with the cathode hot, a voltmeter and ammeter in the filament circuit show no change even when a very heavy discharge is sent through the tube. Positive ion bombardment, if it existed to an appreciable extent, would raise the temperature and, hence, the resistance of the tungsten filament and would therefore be indicated by the instruments. If it were very local and considerable, it would be further indicated by a melting through of the filament at the point in question. The resistance change and local disintegration of the filament have been observed in only those cases where the vacuum, as shown by other effects, such as fluorescence of the glass, has been poor.

Disintegration of the cathode would also manifest itself in blackening of the bulb. Even after running for several hours, the deposit on the bulb is very slight, and what there is may well be entirely accounted for by vaporization of tungsten at the focal spot on the target.

---

[1] For fluoroscopic work with the ordinary tube, it seems preferable to use an interrupted discharge so as to reduce heating of the tube and danger to patient and operator. The phosphorescence of the fluoroscopic screen makes possible frequent interruptions without appreciable loss of light.

N. *The Target the Factor Limiting Allowable Energy Input.*

There is one limitation with the new tube. With a sharp focusing tube and above a certain energy input the tube resistance is unstable, dropping suddenly to perhaps a small fraction of its original value, returning instantly to the old value however upon stopping the discharge or upon lowering it to the limiting value. The cause of this phenomenon appears to be as follows:

With a very high energy input and sharp focusing, the surface of the target melts at the focal spot and volatilizes. Owing to the fact that this tungsten vapor is produced at the focal spot, all of the primary cathode rays pass through it and, by collision, ionize it. This of course decreases the tube resistance. The larger the focal spot the greater is the limiting current. The design of the target also has a great deal to do with the limiting current value, as the face of a thin target is vaporized with a much lower energy input than a relatively thick one. For very short excitation of the tube, the limiting energy input is somewhat larger than for longer periods; but an input which can be carried for a few seconds can be carried indefinitely.

The effect of substituting any other single refractory metal for the tungsten of the target will be to lower the maximum allowable energy input. For the essential properties of a target material are: high density, high melting point, high heat conductivity, and low vapor pressure. Tungsten has a higher melting point and lower vapor pressure than any other metal. Its nearest competitor in point of refractoriness, tantalum, has only about one third of the heat conductivity. Molybdenum and iridium have vapor pressures altogether too high to entitle them to consideration, even if their melting points made them otherwise competitors. Osmium has only about one half of the heat conductivity of tungsten.

The ordinary copper-backed tungsten target would be very difficult to exhaust sufficiently. Otherwise its use might be desirable for certain classes of work, as it would raise the maximum allowable instantaneous energy input.

§ 6. DANGER CONNECTED WITH USE OF TUBE.

There has been in the old tube a certain element of safety in that it could not be run continuously with a very heavy energy input. The new tube, even when focusing sharply, can be operated, for example, on a 7 cm. parallel spark gap with currents as high as 25 milliamperes for hours at a time, and without the slightest attention.

For most purposes, other than diagnostic or radiographic work, there is no advantage in having the tube focus. In case it does not, the above-

DEFENDANT'S EXHIBIT No. 67.

DEPARTMENT OF COMMERCE
UNITED STATES PATENT OFFICE

To all persons to whom these presents shall come, Greeting:

THIS IS TO CERTIFY that the annexed is a true copy from the records of this office of the File Wrapper and Contents, in the matter of the

Letters Patent of

William D. Coolidge, Assignor to
General Electric Company,

Number 1,203,495, Granted October 31, 1916,

for

Improvement in Vacuum Tubes.

IN TESTIMONY WHEREOF I have hereunto set my hand and caused the seal of the Patent Office to be affixed, at the City of Washington, this twenty-sixth day of October in the year of our Lord, one thousand nine hundred and twenty-six and of the Independence of the United States of America the one hundred and fifty-first.

ATTEST:

Associate Attorney

No. of Claims Allowed 33, Title as Allowed Vacuum-Tube

2.60 - 3.50

PETITION

To the Honorable Commissioner of Patents:

Your petitioner William D. Coolidge,

a citizen of the United States, residing at Schenectady,

in the County of Schenectady State of State of New York,

whose Post Office address is c/o General Electric Co., Schenectady, N.Y.

prays that Letters Patent may be granted him for the improvement in

VACUUM TUBES

(Docket No. 17,390),

set forth in the accompanying specification.

And he further prays that you will recognize Mr. Albert G. Davis, of Schenectady, New York, as his attorney, with full power of substitution and revocation, to prosecute this application, to make alterations and amendments therein, to receive the patent, and to transact all business in the Patent Office connected therewith.

William D. Coolidge

TO ALL WHOM IT MAY CONCERN:

BE IT KNOWN, that I, William D. Coolidge, a citizen of the United States, residing at Schenectady, in the County of Schenectady, and State of New York, have invented certain new and useful improvements in Vacuum-Tubes, of which the following is a specification.

My invention relates to vacuum tubes and more especially to tubes operated for the purpose of producing Röntgen or X-rays. The tube which I have produced differs so radically from the tubes of the prior art used for producing Röntgen or X-rays as to amount not so much to an improvement on prior tubes as to an entirely new variety of tube differing both in its principles of operation and in its operating characteristics.

In the Röntgen tube of the prior art, it was necessary that there be at least some free gas in the tube, the reason for which may be explained as follows: The number of ions present in the tube was exceedingly small until a high potential was impressed upon its terminals. The effect of this high potential was to accelerate the motion of the small number of ions originally present, thus causing them, by their collision with gas molecules to produce more ions, and, further, to so ~~direct~~ attract the positive ions that they would bombard the cathode and so cause it to emit electrons. These electrons, directed by the electric forces in the tube, move towards the anti-cathode and in their movement constitute the so-called cathode rays. Upon colliding with the anti-cathode these undergo a sudden change in velocity and so give rise to the Roentgen or X-rays. As the emission of electrons from the cathode was due solely to bombardment by positive ions, and as these positive ions owed their existence to the presence of gas in the tube, it is seen at once that the

Par B

X-ray tube of the prior art was absolutely dependent for operativeness upon a proper amount of gas. Without the presence of sufficient gas to permit a discharge to take place between the electrodes the cathode would not be bombarded by positive ions and so no resulting production of X-rays would occur. The presence of this gas, heretofore considered a necessity in the operation of such a tube, gave rise to certain features of operation of the tube which are obviously very disadvantageous but which have heretofore been accepted by workers in the art as unavoidable evils. I will not here attempt to point out all of the troubles which may be traced to the presence of this gas, but will mention a few of the attendant difficulties.

(a) The pressure of the gas in such a tube is exceedingly variable, and any change in gas pressure is accompanied by a corresponding change in the resistance of the tube and in the penetrating power of the Roentgen rays.

(b) A sufficiently exact adjustment of pressure, to give the desired penetrating power of the Roentgen rays, calls for a great deal of manipulative skill and long experience on the part of the operator.

(c) Besides the slow changes in gas pressure, which can be corrected by the operator, there are other very rapid pressure changes which go on even during a very short radiographic exposure. These cannot be corrected and, as a result, the exposure or fluoroscopic examination is made, not with Roentgen rays of the quality desired, but with whatever approximation to that is allowed by the idiosyncrasies of the particular tube in question, in other words, with a mixture of rays differing perhaps very widely in penetrating power.

(d) The tendency to undergo rapid changes in gas pressure increases with use, until finally the tubes of the prior art show such instability of vacuum that they are no longer useful, even though they may be otherwise in perfect condition.

(e) Many of the positive ions instead of striking the cathode, strike the glass constituting the tube wall around it, and, by their excessive local heating, cause disintegration and cracking of the envelope at this point. This imposes a limitation on the permissible energy input in such a tube.

Per. Fr

(f) Many tubes of the prior art show variability in the location of the focal spot. As the focal spot is the source of the X-ray, its movement during a radiographic exposure, means a blurring of the picture ~~in this direction~~. It is my belief that sudden changes in gas pressure lead to movements of the focal spot.

(g) Some of the electrons coming from the cathode are impeded in their passage to the target by impact with intervening gas molecules and so do not have, upon reaching the target, the same velocity as those electrons which have passed through the entire potential drop from cathode to target without meeting an obstruction. The higher the gas pressure in the tube the greater will be the influence of this effect and, consequently the greater will be the lack of uniformity in the penetrating power of the resulting Roentgen rays.

(h) There is a strong bombardment of the glass, constituting the entire anterior hemisphere, of such a tube, by secondary cathode rays emitted from the anticathode. This causes excessive local heating of the glass and a vigorous emission of secondary X-rays from the bombarded glass. These secondary rays, unless prevented by the use of a proper diaphragm, cause a blurring effect in the radiograph and on the fluorescent screen.

(1) Any electromotive force in the source of current supply for such a tube, in a direction which would make the target function as cathode, must be carefully suppressed, as it otherwise leads to changes in gas pressure.

In order to overcome these troubles met with in the X-ray tubes of the prior art, I remove the cause of the trouble, namely, the gas in the tube, and produce the electrons from the cathode necessary to the production of the X-rays, not by a bombardment of the cathode by positive ions due to ionization of the gas by the voltage impressed upon the tube, but by heating the cathode to incandescence by energy from a suitable source. In tubes made according to my invention I eliminate the action of positive ions as far as it is possible to do so by evacuating the tube to the highest vacuum which can possibly be attained and by thoroughly freeing the electrodes from gas. In the tube of the prior art the pressure of gas was quite appreciable and varied from say one to ten microns (0.001 to 0.010 millimeters) of mercury. With a tube made according to my invention, the tube proper and the electrodes being thoroughly freed from gas as hereinafter described, the pressure of gas may be say five hundredths of a micron (0.00005 millimeter) or lower and in any event lower than that at which the tube would operate as an ordinary Roentgen ray tube. The upper limit of pressure may therefore be placed roughly at say about 0.6 of a micron or thereabout. With such a vacuum in a tube of the prior art so far as I am aware no current whatever would pass in the tube and no X-rays would be produced.

As a cathode I ordinarily use a tungsten filament and this may be conveniently heated by current from a storage battery or transformer with suitable regulating devices so that the temperature of the cathode or filament may be adjusted at will. I have found that electrons will be emitted from such a cathode, which electrons will traverse the space between the cathode and the target under the influence of the electromotive force impressed upon the tube, and by bombardment of the target, will give rise to X-rays. In this new type of tube positive ions appear to play no role whatsoever. The excessively low gas pressure must make their number exceedingly small. The fact that they do not play an appreciable rôle at the cathode is experimentally shown by the fact that the temperature of the heated cathode is not measurably raised by passing heavy discharges through the tube. In the same tube, with gas pressures approximating those used IN tubes of the prior art, the tungsten filament, functioning as cathode, is raised by these same discharges from room temperature to extreme incandescence, and may even be melted by the bombardment of the positive ions.

Gas pressure in the tube being thus eliminated to the highest possible degree, those features of instability in the tubes of the prior art which it can now be seen were due to the presence of the gas in the tube are likewise eliminated.

Furthermore, by static or electromagnetic means I cause the cathode rays or electrons to be focused on the anode or target and this focusing effect is steady and unwavering.

A tube made in accordance with my invention differs from the tubes of the prior art in the possession of most remarkable characteristics. Thus there are no marked changes in the operation of the tube during a considerable length of time, with the result that X-rays may be constantly generated of a much more uniform degree of penetrating power and much more constant in volume and in the location of their source-

or focal spot. The penetrability or in other words the "hardness" or "softness" of the X-rays may be adjusted at will by adjusting the temperature of the cathode. There is practically no fluorescence of the glass of the tube and this is important because it indicates that the glass is not bombarded by secondary cathode rays emanating from the target or anode and is therefore not being locally heated thereby. There is only a more or less negligible production of the secondary X-rays from the glass which form such a useless and disturbing factor in the ordinary Roentgen tube. The voltage consumed by the tube may in certain forms of embodiment of my invention be made to remain more or less constant even though the voltage of the source of current supply varies. The focusing effect is steady and the sharpness of definition of the X-ray photographs is increased. These and other features and advantages of my invention will be better understood by reference to the following description taken in connection with the accompanying drawings. The features of novelty I have endeavored to point out in the appended claims.

In the accompanying drawings, Fig. 1 is a sectional view of a complete tube equipped with one type of focusing device; Figs. 2 to 7 illustrate alternative forms of focusing devices, and Fig. 8 illustrates a modified tube having a constant voltage characteristic.

42

Referring to Fig. 1, showing one embodiment of my invention, the tube or envelop~~e~~ is indicated at 1, consisting as usual of glass, or other transparent material. In the tubular end 2 is sealed an anode 3 which in this case is plate-shaped. It is supported by a stem 4, both anode and stem consisting, preferably, of wrought tungsten. Opposite this anode, which serves also as target, is a cathode 5 adapted to be heated, in this case a filementary

Per F.

spiral of tungsten, tantalum, carbon or other highly refractory material. In this case the filament is wound non-inductively, though this is not essential. It is connected to leading-in wires 6, 7, sealed into a glass support 5, the wires being insulated from each other by little glass tubes 8 as clearly shown. The wires 6, 7 are connected to a source of current, such as a battery 9, or to a transformer, through a regulatable resistance 10. The battery, or transformer secondary, should be well insulated owing to the high potential used in operating the tube. Around the cathode proper is a hollow cylinder 11 consisting of tungsten, aluminum, iron, or other suitable conductive material held in position by springs 12, one of which engages with a little knob 13 on the glass. This cylinder or tube is preferably electrically connected to the cathode by means of wire 14, either inside the tube or brought outside of the tube as shown, and containing in circuit a switch 15. In normal operation the cylinder 11 performs the important function of modifying the static field to focus the cathode discharge, as will be explained.

Instead of being tubular the focusing device may assume various other shapes. It may be a perforated flat disc, as shown at 16, Fig. 2, or a perforated dished or concave disc 17, Fig. 3, or even a simple ring 18, Fig. 4. In fact, even a metallic deposit, such as a film of chemically deposited silver, on the walls of the globe, as shown in Fig. 5 at 19, will act as a static focusing means.

Magnetic focusing means may be used, instead of the static focusing devices, and as shown in Figs. 6 and 7. The magnetic focusing means may take the form of a solenoid, either inside the tube similarly to the static focusing ring, or outside the walls of the tube in the vicinity of the cathode, as diagrammatically indicated in Fig. 6, at 20, or the cathode itself is wound inductively, as shown by cathode 21 in Fig. 7.

In the preparation of the tube the glass is first freed from moisture and gas by heating and other approved methods and the electrodes preferably are freed from gas as by heating them to a high temperature in a vacuum. Exhaustion of the tube is preferably carried on by means of a pump which will remove vapors as well as gases, such as the Gaede molecular pump. For the removal of the last portions of gas from the electrodes and from the glass the tube is operated on the pump. The electrodes should be made of refractory metal such as tungsten so that they will withstand the very high temperatures attainable by operating the tube while connected to the pump, whereby gas may be effectively driven out. In case the usual constriction in the exhaust tube is employed, pumping is thereby greatly delayed. In some cases much time can be saved by omitting the constriction until the tube has been exhausted to [illegible] point where the operation is satisfactory. Carefully dried air can then be admitted and the constriction put in. Upon exhaustion of the dry air it will be found that the condition of the tube, even without further running on the pump, is essentially what it was before air was admitted.

Per L

When the electrodes have been sufficiently freed from gas, particularly the anode which is of large mass relative to the cathode and the tube has been exhausted to a vacuum of about .05 microns (0.00005 millimeters of mercury) or lower it is sealed off from the pump. It may be operated, in accordance with my invention, by closing the battery circuit through the resistance 10 so as to heat the filament 5 to incandescence. When a sufficiently elevated temperature has been reached electrons are emitted by the filament. When a sufficient potential is applied across the tube by completing connection to a suitable source 22, through conductors 23 and 24, current is transmitted, provided the negative terminal of the source is connected to the filament. ¶

L.H. The electrons soon charge the hollow cylinder 11 to a negative potential with respect to the cathode unless the cylinder and cathode are connected. Whether connected or not, the cylinder so modifies the nature of the static field within the tube that the electrons are directed upon a spot of small area upon the anode 3. ¶ In my opinion the focusing action is caused by the electrons tending to move perpendicularly to the equipotential surfaces which may be drawn in the space between cathode and anode. This manner of focusing the cathode discharge is especially effective as the speed of the electrons is relatively low near the cathode and therefore their movement is easily directed by the focusing devices. The focal spot on the anode remains fixed during the normal operation of the tube. This is in sharp contrast to the operation of the ordinary Roentgen tube in which the focal spot often moved about so rapidly as to produce blurring of all lines not parallel to the direction of motion, even during very short radiographic exposures.

E The operation of ~~tubes~~ X-ray devices made in accordance with my invention is markedly affected by the temperature to which the cathode is raised. If the temperature of the filament is low only a small number of electrons escape, and therefore the saturation current through the tube is relatively small. Increasing the impressed voltage on the tube will

B cause substantially no further increase in current. It will increase the velocity of the cathode rays and hence the penetrating power of the Roentgen rays. If the filament temperature on the other hand is very high, further increase of temperature

Pe B
Pei a
a

produces no appreciable effect on the tube characteristics, more electrons being emitted by the filament than can be carried by the voltages employed ~~be carried~~ from one electrode to the other. At higher filament temperatures, the space relations of the elements of the tube such as the distance between cathode and anode, the location of the focusing means relative to the cathode, the diameter of the opening in the focusing device, etc. constitutes a current limiting factor, as will be later explained.

Except for these limiting cases, an increase in impressed voltage will in general cause an increase in discharge current and in the potential drop in the tube, thus increasing the penetrability of the X-ray.

However, by giving the cathode its main extension in the direction of the axis of the tube, and also suitably proportioning and locating the focusing device, a most important new characteristic may be attained. Such a construction is shown in Fig. 8 in which a filament 25 extends nearly through the whole length of tube 26, being anchored at its tip by a support 27. With a low impressed voltage, only that part of the filament ~~26~~ 25 nearest the anode will furnish the electrons necessary to carry the discharge current. With higher impressed voltages, a progressively greater part of the filament will contribute electrons. The increase in the number of electrons thus rendered available by the increase of impressed voltage and the accompanying change in distribution in the static field, tends to reduce the tube resistance and thus counteract the tendency of the higher impressed voltage to increase the potential drop through the tube. A tube thus constructed, therefore, exhibits within certain limits an important new characteristic of operating with a substantially constant potential drop over a range of variable

B

impressed voltage. The advantages of this new characteristic of the tube are manifold. A most important advantage is gained in the homogeneity of the X-rays obtained when the tube is operated from a current source, in which the voltage varies periodically, as, for example, when a transformer, induction coil or a rectifying device such as a mechanical selector, are used which gives current impulses of variable voltage.

My novel apparatus, therefore, has the following valuable and striking characteristics. First, the resistance of the tube, and, hence the penetrating power of the Roentgen rays produced in the tube, may be controlled with certainty, and may be instantly increased or decreased at will, by raising or lowering of the temperature of the cathode; second, a much more homogeneous bundle of X-rays can be produced even though a several-fold increase, or decrease of gas pressure takes place in the tube, providing the pressure remains within the limits above indicated; third, as the discharge can pass through the tube only when the heated electrode is made the cathode, the tube may be operated on alternating current almost equally as well as on direct current; fourth, if desired, a tube may be proportioned to give over a predetermined range of impressed voltage X-rays of substantially uniform penetration.

E

The operator is thus enabled to determine, with a properly calibrated ~~tube~~ device, from a curve, or chart, just what current values and voltages he needs for a given purpose, and may be sure that when he has prepared his patient he can get exactly the service he requires from his tube without troublesome and dangerous experimentation.

One of the main causes for the uniformity of the penetrability of the X-rays is to be ascribed to the fact that the operation of the tube is not dependent upon positive ion bombardment of the cathode. Another cause is its complete independence of vacuum changes within the permissible range of pressure. It will also be noted that with the high vacuum existing in the tube, the mean free path between gas molecules is much greater than the distance between anode and cathode and, therefore, very few electrons can collide with gas molecules in passing from cathode to anode, therefore, practically all of the electrons reach the target with uniform velocity. Because of the low gas pressure the number of positive ions is so small that the filament is not heated at all by bombardment. Even when a very heavy discharge current is sent through the tube, a voltmeter and ammeter in the filament circuit indicate no change in the resistance and hence the temperature of the filament. Another observation, which has a similar significance, is that at low filament temperatures, where the electrons emitted by the cathode are all used in carrying current, a several-fold increase in voltage brings substantially no accompanying increase in the discharge current. This could hardly pertain, in case positive ions played an appreciable rôle, for increased voltage would mean higher velocities, and hence, a greater emission of electrons which, in turn, would mean an increase in the discharge current.

Per B

A

The wall of the tube exposed to the anode is not heated by secondary cathode rays from the anode, thereby removing the limitation formerly imposed by local tube heating. Tube fluorescence due to secondary cathode rays is likewise absent. Not only are current carrying limitations thus removed but it should also be noted that a marked gain of efficiency is secured in the tube. For example, in the former type of tube with a platinum target, about three-fourths of

A

many electrons left the target as "secondary cathode rays" as were received by it in the form of primary cathode rays. The elimination of secondary cathode rays also greatly improves the tube as the secondary X-rays produced by the secondary cathode rays striking the tube were a serious disturbing factor as already mentioned.

While I have described and illustrated specific forms of tubes embodying my invention, I wish it to be understood that various changes and modifications may be made in the tube within the scope of my invention. As already indicated the ~~specific~~ spacial relations of the elements of the tube affect its characteristics. For example, increasing the distance between the front of the focusing device and the incandescent cathode increases the resistance of the tube; decreasing the opening in the static focusing ring or tube increases the resistance of the tube. Decreasing the distance between cathode and anode lowers the resistance of the tube, but this effect is probably not to be ascribed to any considerable resistance change due to linear separation of the electrodes but to the fact that the glass walls of the tube are charged negatively during operation and thus act as though they represented an extension of the focusing device. Bringing the cathode nearer to the anode therefore, would have an effect similar to that caused by bringing it nearer to the front of the focusing tube or ring.

What I desire to secure by Letters Patent of ~~the~~ United States, ~~is~~:-

Per B

1. In a device ~~tube~~ for the production of X-rays, the combination of a ~~the~~ tube ~~proper~~ provided with electrodes, the vacuum in the tube being so attenuated as practically to eliminate the production of positive ions, and means for generating electrons at the cathode or negative electrode substantially independently of the voltage impressed upon said electrodes.

C

C

Per A

Sub-B¹

~~2. A Roentgen ray ~~tube~~, comprising an envelope, and cooperating electrodes therein, at least part of one of which is adapted to be maintained at incandescence, said envelope having a vacuum more highly attenuated than the working vacuum of a Roentgen tube provided with an unheated cathode.~~

Cl'd

B

3. An electrical vacuum discharge tube, comprising an envelope, ~~and~~ cooperating electrodes ~~therein~~, at least part of one of which is adapted to be maintained at incandescence, the vacuum within said envelope being so high that ~~the cathode is not sensibly heated by a discharge current through the tube~~.

Insert B²

4. An electrical vacuum discharge tube, comprising an envelope, cooperating electrodes therein, one of which is adapted to be independently heated, and a conducting body surrounding said cathode, said body serving to modify electrostatic forces in the tube, to control the direction of ~~and direct~~ the cathode rays.

Per E

Insert B³

B

5. An X-ray device ~~tube~~ comprising electrodes consisting of tungsten freed thoroughly from gas, the negative electrode being adapted to be independently heated, at least in part, and an enclosing envelope so ~~more~~ highly evacuated ~~than the working vacuum of an X-ray tube provided with an unheated cathode~~.

B

Insert B⁴

Sub B

6. An electrical discharge tube comprising an evacuated envelope, electrodes therefor, the cathode being extended longitudinally and adapted to be heated independently and conductive means in part at least surrounding the space between said electrodes to control electrostatic forces in the tube.

Cl. 6-7

7. An electrical discharge tube, comprising an evacuated envelope, cooperating electrodes therein, the cathode being adapted to be independently heated, and static means near the cathode for focusing the cathode discharge upon the anode.

V. C. 4

8. A Röntgen ray tube, comprising an envelope evacuated to a pressure of less than about .6 micron, a cathode therein adapted to be heated independently of the operating current, a cooperating anode and means for focusing the cathode discharge upon the anode.

Cl. 9

Sub. B

9. The combination of an envelope, cooperating electrodes therein, said envelope being evacuated to such degree that the mean free path between the residual gas molecules is greater than the distance between the electrodes, a source of energy connected to said electrodes, and means for heating at least part of the negative electrode to incandescence.

5

D

Insert D'

C

C

Insert D

10. ③ A Röntgen apparatus comprising an ~~evacuated~~ envelope, D' electrodes therein, external means for independently heating the negative electrode, and means ~~for controlling~~ modifying the static field to focus the cathode discharge upon a spot of small area on the anode.

52

11. A Röntgen tube comprising an evacuated envelope main working electrodes therefor, one of which is of fila-

mentary character, means for heating said filamentary electrode, and an electrical conductor at least in part surrounding the space between said electrodes. ② C'

Insert C'

Per A

12. A Roentgen ray tube comprising an evacuated envelope, electrodes therein, the cathode being arranged to be heated independently, and a focusing device surrounding and electrically connected with said independently heated cathode.

B

13. The combination of a source of current alternating in potential, and a Roentgen-ray tube operatively connected therewith comprising co-operating electrodes at least part of one of which is adapted to independently generate electrons ~~be heated~~, and an envelope therefor evacuated to such high degree that manifestations of positive ions are absent.

B

a

14. A Roentgen ray tube comprising an envelope, cooperating electrodes therein, at least part of one of which may be independently heated to emit electrons, the space in said envelope being so highly evacuated that manifestations of positive ions are absent, means for producing a cathode discharge in said tube and means for controlling the static field in said tube to prevent electrons from striking the ~~glass~~ envelope.

E

Cl. 15

Sub E'

~~15. The combination of a source of current, an X-ray tube having main electrodes connected thereto, the cathode being adapted to be heated at least in part, an envelope surrounding said electrodes, evacuated to so low a pressure that manifestations of positive ions are absent, an independent source of energy for heating the cathode and means for adjusting the heating current to control the resistance of the tube.~~

Per E
E

16. In a ~~tube~~ device for the production of Roentgen rays, the combination of ~~the tube proper~~ a tube evacuated to such a degree that practically no current can pass due to ionizing action of the impressed voltage upon such gases as may remain in the tube, positive and negative electrodes in the tube provided with suitable leading-in conductors, and means for heating the cathode to a high temperature, said means being independent of the impressed voltage.

Insert B7

Insert B8

17. An electrical vacuum tube, comprising a (5) B7 cathode adapted to be heated to incandescence, a cooperating anode (6) B8 and means disposed about an axis passing through cathode and anode for directing the cathode discharge. Cl. 18

Per B
Sub. D3

~~18. An electrical ~~vacuum tube~~ discharge device, comprising an envelope, a cathode adapted to be heated, a cooperating anode, and conductive means surrounding, in part at least, the space between cathode and anode for modifying the static field to focus a cathode discharge.~~

Sub. B9

~~19. The method of producing Roentgen rays which consists in producing an electric discharge between an incandescent cathode and a cooperating anode in a vacuum more highly attenuated than the ordinary working vacuum of Roentgen tubes, and focusing the cathode rays by means of an electrical field.~~

Per B.

~~20. The method which consists in producing an electric discharge between an incandescent cathode and a cooperating anode in a very highly attenuated vacuum, directing the discharge upon a focal surface, and regulating at will, the penetrability of the rays by varying the voltage impressed upon said electrodes.~~

[illegible]

~~21. The method of regulating the penetrability of Roentgen rays produced by a discharge from an incandescent cathode in a very high vacuum, which consists in varying the temperature of said cathode.~~

W. D. Coolidge, S. No. 766,549, filed May 9, 1913,

Vacuum Tubes.

E. B. Moore

Commissioner of Patents.

The following references are made of record:

"Conduction of Electricity Through Gases", second edition, by Thomson, Cambridge University Press,
"Practical Radiography", third edition, by Isenthal and Ward, published by Dawbarn and Ward, London,
"Annalen der Physik und Chemie", Vol. 14, 1904, page 425-468, Wehnelt,
"Annalen der Physik und Chemie", Vol. 20, 1883, page 705.

These references may be seen in Division 16 of this Office.

Page 7, line 6, "8" should be 8'.

Page 10, lines 2 and 3, respectively, a comma should be inserted after "can" and "employed".

The source of current 22 should be shown conventionally in Figure 1.

The state of the art is generally shown in the above references. The two references in Annalen der Physik und Chemie show that it is old to heat the cathode in a highly evacuated tube. Attention is particularly directed to Figures 12 and 13 of Volume 20 and the description pertaining thereto, page 133, Article 90. Also see Articles 91 and 92, Volume 21.

Attention is directed to Chapter VIII in Thomson on "Ionization of Incandescent Solids" and particularly Articles 103 to 106 therein in which several experiments are described showing that the generation of electrons is independent of the voltage between certain limits (bottom page 193) and that "the negative electricity from the hot wire is carried by the same carriers as the cathode rays, i. e., by 'corpuscles', those small negatively electrified bodies of constant mass which in all the cases yet investigated act as the carriers of negative electricity in high vacua" (bottom page 197). Thus it is clear that the action involved in the references is identical with that which would be obtained with cathode rays in an x-ray tube.

Claims 1, 2, 3, 5, 8, 9, 11, 13, 15 and 16 are each rejected on Thomson or the Annalen der Physik und Chemie references for the reasons given.

Claims 4, 6, 7, 10, 12, 14, 17, 18 which include the electrostatic cathode-stream directing means are rejected on the same references and grounds, in view of Practical Radiography, cited, which discloses the idea of "coating the neck of the tube with a strip of tinfoil in the plane of the cathode edge, and connecting the tinfoil ring through a small gap with the cathode terminal". It is true that no suggestion is made in this reference of the use to which applicant has put his similar arrangement, but the discovery of a new function for an old construction is, of course, unpatentable. Furthermore, it is a well known fact that the cathode itself has a pronounced electrostatic effect in directing the cathode stream and this effect has been determined to a mathematical exactness. See Thomson, above cited, Articles 339 and 340 and incidentally see top page 120 and middle page 600. The effect of a conductor surrounding the cathode a short distance away and connected thereto, as in the reference cited, would of soufse be similar. The fact that a small gap exists in the connection between the tinfoil and the cathode in the reference is immaterial since sparks pass freely across the gap and maintain the tinfoil at the same potential as the cathode.

Claims 2, 9 and 15 are rejected on practically any reference in the art since the cathode is usually heated to the point of incandescence by the operation of the tube.

In connection with claim 11 it is noted that cathodes of filamentary character are well known in the art and the use thereof involves no invention.

Claims 19 to 26 are rejected as being purely functional since they do not recite a true method or process but merely the mode of operation of the apparatus disclosed. Furthermore, these claims are met by the references cited.

Examiner, Division XVI.

CSG

PAPER NO. 3
AMENDMENT. a

UNITED STATES PATENT OFFICE.

In re Application of :
WILLIAM D. COOLIDGE, :
Serial No. 766,549, : **VACUUM TUBE**
Filed May 9, 1913, :
Room No. 109. :

a

Honorable Commissioner of Patents,

Sir:-

In response to the Office Action of July 23, 1913, please amend the above-entitled application as follows:-

✓ Page 7, line 6, change "8" to - 8' -

✓ Page 10, line 2, after "can" insert - be carried, -

✓ Line 3, after "employ" place a comma and cancel "be carried"

✓ Claim 2, line 1, before "tube" insert - ray -

✓ Claim 12, line 1, before "tube" insert - ray -

✓ Claim 14, line 1, before "tube" insert - ray -

✓ Add the following claims:-

a'
2 C²

25. ~~27.~~ The method of depriving a metal body of occluded gas which consists in subjecting said metal body to electron bombardment in a maintained vacuum.

26. ~~28.~~ The method of removing gas from a metal which consists in operating said metal as anode to an electron discharge in a highly evacuated space and progressively removing gas from the space near said anode as liberated by said discharge.

~~29.~~ The method of preparing an anode for electron discharge apparatus which consists in subjecting the same to electron bombardment in a maintained vacuum.

28. ~~30.~~ ~~The method of preparing an electron-discharge device comprising a gas-tight envelope, an electron-emitting cathode and an anode, which consists in evacuating said envelope, then subjecting said anode to an electron-discharge while continuing the evacuation to completely free the same from gas, and finally sealing the envelope when the gas pressure is so low that the normal operating electron discharge cannot produce appreciable gas ionization.~~

29 ~~31.~~ ~~The method of preparing an electron-discharge device comprising a gas-tight envelope, an electron-emitting cathode and an anode, which consists in evacuating said envelope, then subjecting said anode to an electron-discharge with an energy input sufficient to heat the same to incandescence, continuing the evacuation until the residual gas present in the envelope is below the pressure at which appreciable ionization takes place at the normal operating electron current, and then sealing the envelope.~~

Insert B" Per B

~~32. An electron discharge apparatus comprising a gas-tight envelope, an electron-emitting cathode and an anode freed from gas ionizable by electron bombardment, said envelope being evacuated to below the pressure at which gas ionization by collision takes place at the working current and voltage of the apparatus.~~

~~33. An electrical discharge device comprising an envelope, and cooperating electrodes at least one of which has been deprived of gas disengagable~~

by electron bombardment, said envelope being evacuated to such low pressure that conduction of current can take place in the evacuated space independently of gas ionization.

34. An electrical discharge device comprising an evacuated envelope, an electron-emitting cathode, and an anode deprived of occluded gas by electron bombardment in a maintained vacuum, the gaseous pressure in said envelope being low enough to enable an electron discharge to take place without substantial gas ionization.

R E M A R K S

Applicant's attorney has carefully perused chapter 8 of Thomson's"Conduction of Electricity through Gases" (1906 edition). This chapter no doubt contains a very comprehensive study of the work of the investigation in the field of vacuum tubes provided with incandescent cathodes. It is true that investigators have for a great many years observed that there is a unilateral conductivity between a heated electrode and an unheated electrode in an evacuated space. It is a significant fact, however, that no one ever produced a useful X-ray tube provided with an incandescent cathode. The Examiner is no doubt aware that in order to produce X-rays of high enough penetrating power to even pass through the glass of the tube, very high voltages are necessary running in the large commercial X-ray tubes up to 100,000 or even 150,000 volts. The current also is considerable, as heavy anodes may be melted in a high-powered tube. By carefully perusing the article and referring to the original literature from which the observations were obtained, it at once becomes obvious that all the experiments were carried on at very low voltages and at extremely minute currents. For example, in the curves given on page 194 which illustrate the relation between the saturation current and the temperature expressed in degrees centigrade, it will be observed that the current values vary between zero and 200×10^{-9} amperes (.0000002 amperes maximum), and on page 195 a statement occurs that in one particular case the current amounted to about 4×10^{-4} at a temperature of 1500° C. By a perusal of the original literature it will be observed that the current had to be maintained at these extremely low values in order to prevent destructive gas ionization. Applicant's attorney has by diligent search extending not only through the literature cited, but through a wider field, not been able to find a single instance where a current of as much as a few milliamperes has been used in a device of the above character with a voltage of as much as, say, 200 volts.

In all the devices described in the literature anodes of such metals as platinum, carbon or even aluminum, have been used and it is impossible to free materials of this kind from ionizable gas by the methods used by the experimenters. An experiment is described on pages 192-193 of Thomson's book in which it is stated that the pressure is "reduced as low as possible, say to .001 mm. of mercury." The present applicant exhausts to a pressure of .00005 mm. of mercury, or even lower. The gas in the electrodes is even more harmful than the gas in the space in the tube. The early investigators either did not realise or did not have means available for completely removing gases from the anodes, in fact, actually believed that the presence of gas to be necessary for the discharge between the heated and unheated electrode.

The present applicant carefully frees the anode from occluded gases by operating the device on the pump for considerable time while continuing evacuation, as particularly described on page 8 of the specification. It is not merely a matter of heating the electrodes in a vacuum as this alone is not sufficient. In fact, applicant recommends preheating the electrodes in a vacuum but distinctly states that in addition to this heating it is necessary to subject them to the discharge incidental to the operation of the tube while continuing the pumping.

When the gases have not been completely removed from the electrodes or the space not sufficiently evacuated positive ionization takes place by collision of the electrons with the gas molecules which at first is made manifest by erratic readings on the measuring instruments and, if the impressed voltage is increased, by blue glow in the tube, electrical disintegration or "sputtering" of the cathode and also heating of the cathode by bombardment with positive ions. In applicant's device all these phenomena are absent even with currents many thousand times greater than the maximum currents possible in the devices described by Thomson and at voltages for which thus far no limit has been found. In the ordinary operation of the device described in the specification voltages up to 150,000 volts are in everyday use. The discharge current varies directly with the $\frac{3}{2}$ power of the impressed voltage and is independent of the vacuum.

This explanation has been carried to considerable length so as to make clear at the outset that there are remarkable differences between the present apparatus and the devices described in chapter 8 of Thomson's book.

The other articles in the Annalen der Physik und Chemie are mere cumulative references and anything that has been said above also applies to those articles.

In view of these facts it is not seen how claims 1, 2, 3, 5, 8, 9, 11, 13, 15, 16, can be considered to be met by the references cited. In no case could any of these prior devices have been used for the production of X-rays, in fact, it did not even occur to anyone as far as the references show to attempt to use them for this purpose. While applicant's invention includes more than an X-ray tube it undoubtedly does include an X-ray tube which produces a number of new and useful results and which operates in a different manner than any of the X-ray tubes heretofore produced. These new results have already been sufficiently set forth in the specification and therefore it should not be necessary to repeat them here.

The article in "Practical Radiography" appears to have no bearing whatever on the present case. The tinfoil coating on the neck of the tube is for the purpose of discharging static charges upon the glass and not for the purpose of focusing or in any way influencing the discharge itself. In fact, in an ordinary X-ray tube the cathode rays have an exceedingly high initial velocity and therefore while influenced by the curvature of the cathode would not be appreciably influenced by the static field near the cathode. In the present case the velocity of the electrons emitted by the hot cathode is low and therefore are influenced but little by the shape of the cathode but greatly influenced by the static field. Unless the Examiner can point out some reasons not obvious from a perusal of the article cited it is respectfully requested that the reference be withdrawn.

As to claim 11, it is believed that as the application of a filamentary cathode to an X-ray tube is new the combination is a new one notwithstanding the use of a filamentary cathode in some entirely different type of electrical device. Reconsideration of this claim is therefore requested.

Reconsideration of method claims 19 to 26 is also requested. These claims while including certain features of the apparatus include more than this, namely, positive acts to be performed in connection with the operation of the tube, such as the regulation of filament temperature, the impressed voltage, the generation of electrons at the cathode, etc. Applicant's invention includes more than a certain structure which is merely connected in circuit. He accomplishes in a positive, regular manner the control of the penetrability of the rays and the quantity of the rays which had to be left to chance in the former type of X-ray tubes.

Additional claims have been added to more completely cover such broad features of applicant's invention, as the removal of gas on the pump from the electrodes by an electron discharge, and in general, devices operable at high currents and voltages with a pure electron discharge, whether X-ray tubes, rectifiers, relays or any other type of discharge device.

Reconsideration of the Examiner's requirement to illustrate the source 22 conventionally is respectfully requested. This source furnishes either direct or alternating current and to this end may be a high potential synchronous rectifier or an ordinary transformer, or indeed, a source of unsymmetrical current such as an induction coil. It is not clear to applicant's attorney what conventional designation to use.

Favorable reconsideration is respectfully requested.

Respectfully submitted,

Albert G Davis

Attorney for Coolidge.

All communications respecting this application should give the serial number, date of filing, title of invention, and name of the applicant.

DEPARTMENT OF THE INTERIOR
UNITED STATES PATENT OFFICE
WASHINGTON Jan. 7, 1914.

Mr. Albert G. Davis,
C/o General Electric Co.,
Schenectady, N. Y.

Please find below a communication from the **EXAMINER** *in charge of the application of*

W. D. Coolidge, S. No. 766,549, filed May 9, 1913,
Vacuum Tubes.

Thomas Ewing
Commissioner of Patents.

This is in response to amendment filed Oct. 16, 1913.

Page 10, line 21, "22" should be 25.

It is not understood how the positive ions are directed as described in line 23, page 1. This should be made clear.

The statements at the bottom of page 9 and top of page 10 are apparently too broad. As stated in the paragraph beginning line 10, page 10, an increase in voltage ordinarily produces an increase in discharge current and some increase in current, however small, would be produced in the two limiting cases described. It is suggested that the statements be modified by inserting the word substantially before "no" in line 29, page 9, and in inserting the word appreciable before "effect" in line 1, page 10.

In claim 1 the word "substantially" should be inserted at the beginning of the last line.

766,542 -- 2.

The following references are added to the record to show specific instances of independently heated cathodes in vacuum tubes:

VonLieben et al, 1,038,910, Sept. 17, 1912,
179 - 171,
German, 254,586 of 1912, 250 - 35,
Moore, 1,010,662, Dec. 5, 1912, 250 - 35, X.

The expression "more highly attenuated than the working vacuum of a Roentgen tube provided with an unheated cathode" in claims 2 and 5 is merely relative and is objected to as being indefinite.

Claim 2 is again rejected on the references of record on the ground that practically all cathodes in Roentgen tubes are heated to incandescence during operation.

Claim 3 is rejected and claim 2 is further rejected on the German patent 254,586, cited. In this reference the cathode is heated by a separate source to produce ionization instead of by bombardment of positive ions. Hence the cathode would not be sensibly heated by a discharge current. The tube in the German reference is not shown as a Roentgen tube, but it might be used as such by providing an ordinary target in lieu of the anode A. Claim 2 in no way distinguishes from the reference when so modified.

Claim 4 is rejected on the references and ground of record. As shown by the references of record and those cited it is old to heat the cathode independently in vacuum tubes. The tinfoil ring in the reference, Practical Radiography, while not provided as a means for directing the cathode rays would necessarily perform this function since the structure is substantially the same as that of applicant's Figure 5. The tin-foil ring is connected to the cathode thru a small spark-gap to collect the static charge so that it may be conducted away. The ring would consequently be charged at the same polarity as the cathode. If applicant's directing means operates differently from the reference it must be by virtue of some structural difference and the claims should distinguish by structure rather than by function.

Claim 5 is deemed allowable in substance, upon reconsideration, but is objectionable in form as noted above.

Claims 6 and 7 are rejected on the German patent on the ground that there would be no invention in providing a ring of tin-foil around the cathode as in the reference, Practical Radiography.

Claim 9 is rejected on the German patent 264,588, in view of Note 97, page 105, of the book "Notes on X-light", by William Rollins, published at Boston in 1904, which book may be seen in Room 109 of this Office. This note describes the method of exhausting an X-ray tube by continuing the exhaustion while sending a discharge current thru the tube. A vacuum equal to a millionth of an atmosphere is mentioned which is of substantially the same order as claimed by applicant and there would, of course, be no invention in merely continuing this method to ob-

tain an even higher vacuum. It is held that there would be no invention in applying this method of evacuation to an independently heated tube as shown, e. g., in the German patent. Also see Note 64 of Rollins.

Claim 13 is rejected on the German patent cited on the ground that the discharge tube shown therein could be used as a Roentgen tube by making the anode in the form of a target. Positive ions are comparatively absent (as in applicant's tube) in the German reference and the other references which employ an independently heated cathode.

Claims 17 and 18 are rejected on the references of record and on the ground more fully explained above.

Claim 19 is thought to be allowable in substance. One step in the method has been omitted from the claim, however, and it is suggested that line 2 be amended by inserting "independently producing incandescence of the cathode", after "in" and in changing "an" to the, same line.

Claims 20, 21 and 22 are rejected as merely reciting the method ordinarily employed in operating an x-ray tube in which the cathode is heated to incandescence by the bombardment of positive ions. As described on page 13 of the book by Thomson, of record, a stage is reached in the operation of all vacuum tubes where there is no appreciable increase of current when the potential difference is increased. At such stage increase of voltage would merely increase the velocity of the ions and hence the penetrability of the rays.

Claim 22 is indefinite in the relative expression "more rarified than the ordinary Roentgen tube vacuum".

Claim 24 is allowable in substance but objectionable in the negative limitation in line 4. This objection could be overcome by changing "without" to ", preventing" in line 4.

New claims 27 to 31 are rejected on the Note 37 in Rollins, above cited, which fully anticipates the method here recited.

Claims 32 to 34 are rejected on the same reference. The method disclosed in the reference being the same as employed by applicant, there is no apparent reason why the process could not be continued until the pressure is "low enough to enable an electron discharge to take place without substantial gas ionization".

Claims 8, 10, 11, 12, 14, 15, 16, 23 and 25 are allowable as at present advised.

Wm A Kinnan
Examiner, Division XVI.

UNITED STATES PATENT OFFICE

In re Application of :
WILLIAM D. COOLIDGE, :
Serial No. 766,549, : **VACUUM TUBE**
Filed May 9, 1913, :
Div. 16, Room 109 :

Honorable Commissioner of Patents,

Sir:-

In response to the Office Action of January 7, 1914, please amend the above-entitled application as follows:-

Page 1, line 23, cancel "direct" and substitute - attract -

Page 9, line 29, after "cause" insert - substantially -

Page 10, line 1, before "effect" insert - appreciable -

Line 21, change "22" to read - 25 -

Page 12, line 19, after "brings" insert substantially -

Page 13, line 11, correct the spelling of "spacial"

Claim 1, line 1, cancel "tube" and substitute - device -

Cancel claim 2 and substitute the following claim:

B'

2. An X-ray device comprising a gas-tight envelope, the space within ~~said envelope~~ being exhausted to a pressure at which substantially no gas ionization occurs, a cathode, an anode, and means for generating electrons at the cathode, the current

transmitted by said device with a given cathode temperature being independant of the voltage over a range of impressed voltage values. Cls 3-5 fol

Claim 3, line 2, cancel "and"

Same line, cancel "therein"

Lines 5 and 6, cancel "the cathode is not sensibly heated by a discharge current through the tube" and substitute - evidences of positive

B2 ionization are substantially absent during operation and means for focusing the discharge -

Claim 4, line 6, after "rays" change the period to a comma and add - the residual gas in said envel-

B3 ope being insufficient to produce appreciable ionization by collision during the operation of the tube. -

Claim 5, line 1, cancel "tube" and substitute - device -

Line 4, cancel "more" and substitute - so -

Same line, cancel "than the"

Cancel lines 5 and 6, and substitute

B4 - that evidences of positive ionization are substantially absent during the operation of the device -

Cancel claims 6 and 7, and rewrite as follows:

B5 6. An electrical discharge device comprising an envelope, the space within said envelope being evacuated to a pressure below the value at which appreciable positive ionization can occur, electrodes therefor, the cathode being adapted to be heated independently of energy transmitted by said device and conductive means in part at least surrounding the space between said electrodes to control electrostatic forces in the tube.

7 11 7. An electrical discharge device comprising an evacuated envelope the residual gas in which is insufficient to conduct current between ordinary unheated electrodes, a cathode adapted to be independently heated, an anode from which gas is not disengagable during the operation of the device, and means near the cathode for maintaining a static field focusing a cathode discharge upon the anode. Cl. 8 fols

✓ Claim 8, line 1, before "tube" insert - ray -

✓ Cancel claim 9 and rewrite as follows:

B 6 9. A Röntgen ray device comprising the combination of an envelope evacuated to a pressure at which positive ionization is substantially absent during the operation of the device, an electron-emitting cathode, an anode and a source of energy connected to said electrodes having a voltage in excess of the minimum value at which the current is substantially independent of the voltage. Cls. 10-14 fol

✓ Claim 13, line 2, after "tube" insert - operatively connected therewith -

✓ Line 4, cancel "be heated" and substitute - independently generate electrons -

✓ Claim 17, line 1, after "comprising" insert -

B 7 an envelope the space in which is exhausted to below the pressure at which residual gas will conduct current,

Line 3, after "anode" insert -

B 8 substantially deprived of gas evolvable by electron bombardment, -

✓ Claim 18, line 1, cancel "vacuum tube" and substitute - discharge device -

Same line, after "comprising" insert - an envelope,

98

Cancel claim 19 and rewrite as follows:

~~19. The method of producing Roentgen rays which~~ consists in independently heating the cathode to incandescence, producing an electric discharge between the incandescent cathode and a coöperating anode in a vacuum so highly attenuated that evidences of positive ionization are substantially absent during the passage of current, and focusing the cathode rays by means of an electrical field. Cls. 20-24 fol

(B) Per C

Claim 22, lines 3 and 4, cancel "more rarefied than the ordinary Roentgen tube vacuum" and substitute so attenuated that electrical conductivity of the residual gas is substantially absent, [redacted]

(correct) B10

Claim 24, line 4, cancel "without" and substitute - while preventing -

Cancel claims 20, 21, 32, 33 and 34, renumber the remaining claims and add the following:-

Per L

B11

30. The process of operating an X-ray device comprising a gas-tight evacuated envelope, a cathode and an anode, which consists in generating electrons at the cathode independently of current passed by said device while preventing any accompanying manifestations of positive ions, ~~and~~ impressing on the electrodes a voltage at least as high as the value at which substantially all of the electrons are utilized, whereby the current becomes substantially independent of the impressed voltage., (4)

L

not L2

31. An X-ray device comprising a gas-tight envelope, an electron emitting cathode, and an anode deprived of ionizable gas, the space in said envelope being evacuated to a pressure at least as low as five hundredths of a micron of mercury pressure, the

current transmitted by said device with a given electron-emissivity of the cathode being substantially constant with an impressed voltage variable over a working range.

F 3 Cl. 33

REMARKS

In a previous amendment the nature of applicant's fundamental improvement in Roentgen tubes has been quite fully discussed and therefore will not be repeated at length. Attention, however, is directed once more to the fact that in applicant's tube all evidences of positive ionization such as luminescence of residual gas, conductivity in the space, glass fluorescence, variability of electrical characteristics and others are entirely absent. The term "ionization" has become well understood by scientists working in this field to imply some or all of these phenomena, depending upon the voltage, current and other conditions. For example, in a device such as described in Moore patent #1,0[illegible],568 the light emitted by the gas column is accepted evidence of positive ionization, and, in fact, the Moore patent distinctly states that gas is ionized and rendered luminous by the electric energy passing through the tube. In devices such as described in U. S. patent #1,038,910 and German patent #254,538, the presence of a blue glow or haze in the space within the tube and the electrical characteristics of the device indicate positive gas ionization. Altho these phenomena are not described in the patents these gas ionization tubes are well known in the art, and it is stated repeatedly in each patent that the operation is by virtue of a gas discharge.

The U. S. patent #1,038,910 mentions, lines 55-56 page 1, the "formation of an artificial dark space near the cathode and thus of a space where the number of ions is small". The German patent [illegible] states that an electropositive substance is introduced into the tube "whose vapor wholly or partly assumes the conduction of the current". The patent very clearly indicates that the object of the invention is to lower the discharge potential by the presence of metal vapors which are ionized.

The descriptive matter in a book "Notes on X-Light" by Rollins, referred to by the Examiner, merely discloses the well known fact that gas is "cleaned up", that is rendered inactive in some way by the passage of an electrical discharge in a highly evacuated space. This gas is not removed from the tube and it is stated by Rollins that if such a tube is

> "allowed to rest for a time, it will be found in sending a current through it that the resistance is less - - - - - - - - Gas has come to the surface from the interior, furnishing particles on which the charge rides the field between the terminals."

Rollins explains that under some conditions the vacuum may be reduced to a millionth of an atmosphere. This is about the lowest pressure at which current at the highest voltage will be conducted by residual gas and applicant operates well below this pressure. Rollins could not operate below this pressure while applicant is obliged to operate below this pressure to prevent destruction of the incandescent cathode by bombardment with positive ions.

Neither does Rollins disclose the method of depriving the anode of ionizable gas as set forth by claims 27 to 31. It is true that in the ordinary X-ray tube gas is disengaged from the anode, (in fact, the operation of the tube partly depends upon the evolution of gas from the anode) but the anode is never completely deprived of gas as the removal of gas from the envelope is not being continued. In other words, the anode is not being subjected to the [illegible] removing electron bombardment in a maintained vacuum. As described in the specification it is one of the essential steps in the preparation of applicant's tube to subject the electrode to electron bombardment while on the pump.

Most of the claims have been amended to more clearly distinguish over the references by stating that the vacuum is below the pressure at which conduction of current by gas can occur or, in other words, at a pressure at which positive ionization is absent and have been in other respects improved.

The present invention of Dr. Coolidge, the present applicant, has been commented on by many scientific publications. Space forbids reference to more than two.

In an article by Dr. Kerschbaum in Die Naturwissenschaften for July 3, 1914, page 654, the disadvantages of the old type of X-ray tubes are very fully described and it is pointed out that their operation depend upon positive ions caused by gas molecules by collision. He points out various disadvantages such as the variation of the hardness of the rays during a single current impulse, the vaporization of the electrodes, etc. He goes on to say:

> "All these disadvantages now appear to have been removed to a comprehensive extent in a new vacuum tube which has recently been constructed by W. D. Coolidge and now has been placed in trade by the General Electric Company. Coolidge recognized that the presence of gas was entirely responsible for the disadvantages of the formerly used X-ray tubes."

He goes on to describe the construction of the tube and the fact that a vacuum 100 to 1000 times better than that in the usual tubes is produced. After describing the functions of the hot cathode he states as follows:

> "By realizing simultaneously both of the above named conditions of construction a vacuum tube is produced in which a pure electron discharge can be initiated and maintained, a result which has not been realized by the constructions employed either by Wehnelt and Trenkle, nor by Lilienfeld and Rosenthal."

The various advantages of the Coolidge tube are fully described, and the article closes with the statement that a remarkable advance has been made in this field.

The Examiner is also respectfully referred to an article by Lewis Gregory Cole, M.D., one of the leading X-ray experts, in the Archives of the Roentgen Ray, March, 1914, entitled "Diagnostic & Therapeutic Value of the Coolidge Tube". The following paragraphs are quoted from this article:-

> "On December 27th last the author had the honour of introducing to an assembly of his American associates a man who has accomplished more for the advancement of this science than anyone except Roentgen himself.
>
> \- - - - - - - - - - - - -
>
> "He believed that if a tube could be devised which should be entirely free from gas many of the disadvantages of the ordinary tube would be removed. He introduced a cathode and anode of tungsten, supported by the sister metal molybdenum, which substances are more readily freed from gas than the metals used in the ordinary tube. In this way he was able to procure a vacuum 1,000 times more attenuated than that of the ordinary tube. Dr. Coolidge's associate, Dr. Langmuir, found that a tungsten cathode heated in a highly evacuated bulb, would emit a stream of negative electrons, and thus provided the foundation upon which Dr. Coolidge developed his subsequent work."
>
> \- - - - - - - - - - - - -
>
> "Its tremendous output, both for diagnostic and therapeutic purposes, is perhaps the most wonderful advantage of the tube, making it especially useful in the Roentgenkinematography of the stomach and heart and in radiotherapy of deep-seated cancers.
>
> The complete absence of indirect rays in the Coolidge tube is of great scientific interest and of practical value. The positive bodies in the ordinary tube are a useless and harmful by-product, and their elimination suppresses entirely both the intense heating of the tube and fluorescence of the glass walls. In the author's laboratory the tube is already being used for routine diagnostic and therapeutic work."

The various distinguishing features of the Coolidge X-ray tube have been more fully discussed with the Examiner in a personal interview and it is hoped upon reconsideration the claims will be found allowable.

Respectfully submitted,

Albert G. Davis

Attorney for Coolidge.

Paper No. 5

All communications respecting this application should give the serial number, date of filing, title of invention, and name of the applicant.

DEPARTMENT OF THE INTERIOR

UNITED STATES PATENT OFFICE

WASHINGTON Jan. 12, 1915.

Mr. Albert G. Davis,
C/o General Electric Co.,
Schenectady, N. Y.

Please find below a communication from the EXAMINER in charge of the application of
W. D. Coolidge, S. No. 766,549, filed May 9, 1913, Vacuum Tubes.

Thomas Ewing
Commissioner of Patents.

This action is in response to amendment filed Dec. 19, 1914.

The following reference is added to the record:
Rankin, 838,273, Dec. 11, 1906, 250 - 36.

Claim 19, line 3, a comma should be inserted after "incandescence".

The word substantially should be inserted at the beginning of the last line of claim 1, as pointed out in the last Office action.

Claims 10, 11, 12 and 19 are rejected on the newly discovered patent to Rankin, which shows a vacuum discharge tube having a coil of wire surrounding the tube between the cathode and anode for focussing the cathode discharge. In regard to claim 11, which recites a "filamentary cathode", it is noted that the ordinary type of cathode shown in Rankin is the full equivalent of a filament cathode, the two being used interchangeably in vacuum discharge tubes. As clearly showing that either one or the other may be used, attention is directed to the British patent to Reiss; 2,111 of 1911, 1 sheet.

250 - 27, which shows various modifications in some of which is shown the ordinary type of cathode and one of which (Figure 5) shows a filament cathode adapted to be independently heated."

Claims 25 to 29, formerly 27 to 31, are again rejected on the reference and ground of record. As described in the note of Rollins, it is old to operate vacuum tubes by passing a current therethrough during the process of evacuating the tube. This method is held to be the same regardless of how far it is carried, that is, the method is the same whether the process is carried to the point where the anode is only partially deprived of gas or is carried to the point where the anode is completely deprived of gas. Furthermore, it is noted that this distinction which is relied upon in the argument is not brought out in the claims. However, as above indicated, the claims would not be considered allowable even if this distinction were brought out.

The remaining claims are allowed.

Wm A Kinnan
Examiner, Division XVI.

WILLIAM D. COOLIDGE, :
Serial No. 766,549, : **VACUUM TUBE**
Filed May 9, 1913, :
Div. 16, Room 109. :

C

Honorable Commissioner of Patents,

Sir:-

In response to the Office Action of January 12, 1915, please amend the above-entitled application as follows:

Claim 1, line 2, before "tube" cancel "the" and substitute - a -; after "tube" cancel "proper"

Line 5, after "electrode" insert - substantially -

Claim 10, lines 3 and 4, cancel "controlling" and substitute - modifying -

Line 4, after "discharge" insert - upon a spot of small area on the anode -

Claim 11, line 5, after "electrodes" insert - for concentrating a discharge from said cathode upon a spot of small area on the anode -

C'

Claim 19, line 3, place a comma after "incandescence"

Cancel claims 25 to 29, inclusive, and substitute the following claims:-

C.2

Sub D4

25. The method of depriving a metal body of occluded gas which consists in subjecting the metal body to an electron discharge in an evacuated space, the generation of electrons constituting the origin of said discharge being independent of the voltage producing said discharge, and the residual gas being so attenuated that at the given voltage the gas will not conduct the discharge without the independent generation of electrons, and coincidentally removing gas evolved from said metal mass to maintain the gas pressure so low that at the given voltage a discharge will not occur without the independent generation of electrons.

26. The method of depriving a metal body of occluded gas which consists in operating the metal body as anode for a high voltage discharge originating at a cathode which generates electrons independently of the voltage producing said discharge in a vacuum too high to enable current to be passed at the given voltage without the independent generation of electrons, the energy of the discharge being sufficient to heat said metal body to incandescence, and coincidentally removing gas disengaged by said discharge.

27. The method of preparing an anode for an electrical discharge device which consists in subjecting said anode to a high voltage discharge originating at a cathode which generates electrons independently of said discharge in a vacuum so high that no energy can be passed at the voltage impressed between said electrodes without the independent generation of electrons at the cathode, removing gas liberated by said discharge, and finally sealing the envelope when the residual gas pressure is so low that the device can be operated without appreciable evidence of positive ionization.

28. The method of depriving a metal body of occluded gas which consists in passing between said body used as anode and a cathode heated to incandescence an electrical discharge in a vacuum so high that

~~with the given voltage no energy can be passed without the independent generation of electrons at the cathode, and removing from the evacuated space gas liberated from the anode by said discharge to maintain said high vacuum.~~

~~29. The method of preparing a discharge device comprising an anode of refractory material and a cathode which consists in passing a high voltage discharge between said electrodes, while the cathode is heated to incandescence, in a vacuum so high that with the given voltage no energy can be passed while the cathode is unheated, the energy input of said high voltage discharge being sufficient to heat the anode to incandescence, and removing from the evacuated space gas liberated from the anode by said discharge.~~

Add the following claim:

32. A Röntgen ray device comprising a sealed envelope, the space within which is evacuated to a pressure so low that evidences of positive ionization are substantially absent during the operation of said device, a cathode of refractory metal adapted to be heated substantially independently of a voltage impressed upon said electrodes and a cooperating anode.

Insert F3

REMARKS

cl. 33

The Rankin patent #838,273, and also the Examiner's remarks with respect to a substitution of a filamentary cathode for the cathode shown in the patent, have been carefully noted. Claims 10 and 18 rejected on this patent call for means for modifying the static field to focus a cathode discharge. Whatever may be said of this patent as a reference it certainly does not show a static focusing means. Claim 12 calls for an electrical connection between the focusing device and the independently heated cathode. This is not shown in the Rankin patent.

Claim 11 is expressed in broader language, and in connection with this claim it is pointed out that the Rankin patent shows in addition to the magnetic coil r a diaphragm n opaque to the cathode rays and pierced by a small central aperture whereby the desired small pencil of cathode rays is secured. Clearly it is not the function of the coil r to bring the rays to an actual focus on the anode else why the diaphragm? Claim 11 not only calls for a Roentgen tube and a filamentary cathode, the focusing properties of which were investigated for the first time by Dr. Coolidge the present applicant, but the claim has been amended to indicate that the focusing device actually concentrates the rays upon a spot of small area on the anode and in this manner distinguishes over the Rankin patent.

The Examiner's remarks with reference to claims 25 to 29 have been carefully noted. There appears to be one phase of the situation which the Examiner has not considered. Can a new process be considered a carrying forward of former process if the former process could not possibly be carried any further along the old lines? While gas is being eliminated from the anode by the Rollins process there must be sufficient ionisable gas in the space between the electrodes to spontaneously continue the discharge. As long as this gas is present the anode cannot be completely degasified. The difficulty is much like that of the man who tried to get rid of bugs by the aid of their natural bug enemies. We never quite got rid of bugs.
